Hyperplastic myeloid or erythroid processes, abnormal cell proliferation of acute or chronic leukemic cells will produce uniformly generalized changes in the marrow. Bone marrow punctures with negative results warrant further confirmation and exclusion of technical error.

SUMMARY

In a series of different pathologic conditions, two samples of human sternal marrow were aspirated simultaneously. A comparative analysis of the two samples included the percentage distribution of the different fractions of aspirated marrow, the total number of nucleated cells, percentage distribution of the different cells, and the myeloid-erythroid ratio which were computed and tabulated. There were numerous differences between the two samples, but the trend of cellular differentiation was similar as exhibited by the myeloid-erythroid ratios. The morphologic or pathologic appraisal of any one region of the marrow will usually reveal trends in other portions of marrow throughout the body.

THE RETICULO-ENDOTHELIAL ORIGIN OF THE BONE MARROW PLASMA CELLS IN HYPERSENSITIVE STATES

FRED KOLOUCH, ROBERT A. GOOD, AND BERRY CAMPBELL
MINNEAPOLIS, MINN.

INTRODUCTION

SINCE its description by Cajal in 1890, the plasma cell has been observed by pathologists in the hematopoietic tissue and in the specific lesions of varying clinical conditions. Huebsehmann (1913) studied the spleens of patients dying of various infectious diseases and observed a splenic plasma cytosis resulting from pneumococcic, staphylococcic, diphtheric, and typhus infections. He found little or no increase in splenic plasma cells in cases of fatal miliary tuberculosis, anthrax, or in a luetic stillborn—all overwhelming infections. He associated the plasma cell with the production of antibodies.

Perlzweig, Delruc, and Geschickter (1928) and others since then have associated multiple myeloma, which is apparently a malignancy of the bone marrow resulting in the accumulation of plasma cells, with hyperglobulinemia. Since that time a number of investigations have related the plasma cell to hyperglobulinemia in clinical disease: Osgood and Hunter (1934) in plasma cell leukemia, Markoff (1937) in serum sickness, and Bing and Plum in agranulocytosis (1937). Bing, in various acute and chronic infections, myelomatoses, and other diseases (1940), concluded that the plasma cell of reticulo-endothelial origin was the source of the blood globulin. Fleischhacker (1940 and 1941) made many observations on patients with hyperglobulinemia and found that the bone marrow revealed simultaneous plasmacytosis. His conclusions were similar to those of Bing. Gormsen and Heintzelmann (1941) reported studies of blood globulin and sternal marrow in patients with serum sickness; they found a distinct parallelism between increased marrow plasma cells and hyperglobulinemia and stated that their observations support Bing's theories. Taussig and Somogyi (1940) reported hyperglobulinemia in six cases of granuloma inguinale and stated that it is common in lymphogranuloma inguinale. The presence of plasma cells in the lesions of these two diseases is well known. Kagan (1943) has furnished additional clinical evidence of the relation of globulin level and plasmacytosis.

The relationship of plasmacytosis to globulin and antibody production is substantiated by the experimental literature. Downey's (1911) description of a plasmacytosis in the bone marrow of a rabbit with an incidental nonspecific subcutaneous abscess initiates the series. Doan, Sabin, and Forkner (1930) and Miller (1931) produced omental plasmacytosis by repeated intraperitoneal administration of tuberculo proteins. Rich (1935 and 1936) produced acute splenic tumor in rabbits by horse serum. The characteristic feature was the "acute splenic tumor cell." In similar preparations made in this laboratory we have identified these cells as developing plasma cells. Kolouch (1938)

From the Departments of Surgery and Anatomy, the University of Minnesota Medical School.

studied the plasma cell and found it in the bone marrow of ten species of laboratory animals and also showed that the plasma cell content of the rabbit bone marrow could be experimentally increased by sensitization and shock with *Streptococcus viridans*. He demonstrated the development of the bone marrow plasma cell from the reticular plasma cell in a period of five days and postulated a relation between this transformation and the development of antibodies. Björneboe and Gormsen (1941) described the experimental production of a hyperglobulinemia in rabbits by intensive immunization with different types of formalin-killed pneumococci. They found a concomitant increase in plasma cells in various tissues. They postulated that the increase in the globulin fraction of the blood was due to the increase in antibodies and that this in turn was related to plasmacytosis.

The purpose of the following experiments is to elucidate the relationship of the bone marrow plasma cells to the reticulo-endothelial cell and to the phenomena of sensitivity and shock. Both bacterial and simple protein antigens have been used. Illustrative material from a case of serum sickness is included.

MATERIALS AND METHODS

Rabbits were used in all experiments. Series 1* consists of six rabbits which were injected repeatedly over a period of several months with varying doses of *Str. viridans*. Series 2 contains three rabbits injected subcutaneously with a single dose of 10 c.c. of a culture of *Str. viridans* suspended in agar. After a period of five weeks they were shocked with broth culture of the same organism and serial rib biopsies were made at intervals up to five days. Series 3 consists of sixteen animals which were sensitized to egg white by its injection on alternate days in the following dosages: 1 c.c., intravenously; 0.5 c.c., intravenously; and 1 c.c., intramuscularly. Four animals were killed following the sensitization and four immediately after shock, which was induced twenty to thirty days later by injection of 0.4 c.c. egg white intravenously; four were killed on the fourth day following shock by injection 0.4 c.c. egg white; while the bone marrow of the remaining four was sampled before sensitization, after sensitization, following anaphylactic shock, and periodically thereafter for four days.

The bone marrow was imprinted and stained with Wright-Giemsa.

EXPERIMENTAL RESULTS

The six rabbits of series 1 which were treated over a period of months with multiple injections of *Str. viridans* all showed marked increase in the bone marrow plasma cells, and in some animals there was noted an increase in the reticular plasma cells. These changes were critically followed in the three animals of the second series. Rib bone marrow biopsies were made before sensitization and the elements compared with similar material from the same subjects after sensitization and following shock. The control bone marrows show few reticular plasma cells. These are found to be increased in the biopsies taken after sensitization. They appear as large cells with basophilic, rather muddy cytoplasm with eccentric nuclei characterized by a nuclear pattern similar to that seen in reticular cells (Fig. 2a).

In these preparations the chromatin appears as a fine purplish-violet dust sprinkled on a background of pinkish-yellow karyoplasm (parachromatin). The chromatin granules are uniform, finely divided, round purplish-violet particles.

*The material for this series was obtained from Dr. B. J. Clawson.

Fig. 2.—Photomicrographs of cells showing stages in metamorphosis from reticular plasma cells to Marshalko type plasma cells. Rabbits sensitized and shocked with *Str. viridans*. *a* and *b*, Group of plasmacellular reticulum cells before shock. *c* to *f*, Transformation stages to Marshalko type plasma cells.

Each one is surrounded by and sharply demarcated from the parachromatin which it tends to mask. The chromatin pattern is more condensed and the nuclear membrane slightly thicker than in the unaltered reticulum cell. In the cytoplasm the basophilic spongioplasm occurs as minute masses which are arranged to form small coalescing bars. These elongated clumps are surrounded by and sharply separated from an abundant yellowish hyaloplasm. The arrangement of these two components of the cytoplasm gives it its characteristic canaliculated appearance. In the region of the nucleus there is frequently seen a lighter staining area (increase of hyaloplasm) which suggests a Hof. When occurring alone the cells appear irregularly elliptical, but most frequently they are seen in clumps of five to fifteen cells, the cytoplasmic boundaries then being rather indistinct.

The initial transitional stage occurs within two hours after shock (Fig. 2, *b*). The boundary of the cytoplasm becomes more clearly defined and rounding of the cells is initiated. In the nucleus contraction occurs and a coarser chromatin pattern is to be observed. At four hours shrinkage of the cytoplasm is noted and the basophilia is more apparent than before. By this time dispersion of the cells which previously had been clumped has taken place, and the reticular plasma cells are mixed with the other bone marrow elements. Shortly after four hours the Hof becomes marked. This together with the more condensed nucleus and increased basophilia of the spongioplasm leads to cells more easily recognizable as developing plasma cells. These cells become abundant at five hours. In the ensuing five hours, many of these transform to large plasma cells (Fig. 2, *c*). These are characterized by the eccentric nucleus, a heavier nuclear membrane, blocklike arrangement of the chromatin masses, and a distinct Hof in a still more basophilic cytoplasm. These large plasma cells measure about 20 μ in diameter. Their further evolution consists of shrinkage in the next twelve to thirty-six hours to medium-sized plasma cells measuring about 12 μ in diameter (Fig. 2, *d* and *e*). With this decrease in size, there is accentuation of the nuclear pyknosis, the cytoplasmic basophilia, the Hof, and the initial appearance of the radkern nuclear pattern. These cells are abundant two days following the shock. Continuation of these tendencies results in the small plasma cell (the true Marsehalko type) abundant at four days (Fig. 2, *f*). Some of these cells become, after the fifth day, extremely pyknotic and apparently degenerate, their nuclear structure being obscured by their staining properties.

At no time during this cycle does the reticular plasma cell exhibit phagocytic properties, though other cells of the reticulum are seen to have ingested bacteria and erythrocytes.

To serve as control for the bacteremia and local infection of the first two series, as well as to test the general nature of the phenomenon, the sixteen rabbits of series 3 were sensitized to egg white and studied before and after shock. The observations differ little from those obtained using *Str. viridans* as antigen. In the four animals killed before shock, a massive increase of plasma-cellular reticulum cells may be seen (Fig. 3, *a*). As before, the cells appear in clumps and show morphology identical to those previously described. In the four animals that died immediately upon shock, no change from the pre-

shock picture is noted. Those which were killed four days after shock show marked plasmacytosis of the bone marrow (Fig. 3, *b*). Serial biopsies of the remaining four at 2,4,8,14,24,48,72, and 96 hours, as well as pre- and post-sensitization controls, confirm in all respects the transformation from the reticular plasma cell to the plasma cell previously described (Fig. 1).

That this same transformation from reticular plasma cell to plasma cell occurs in human beings is shown in Fig. 4, which is a blood smear taken from a boy suffering from serum sickness resulting from the administration of tetanus antitoxin.

Fig. 3.—Bone marrow imprints from rabbit sensitized to egg white. *a*, Clumped reticular plasma cells before shock. *b*, Marshalko type plasma cells four days after shock.

Fig. 4.—Illustration of intermediate stages between reticular cells and plasma cells as seen in blood smear of patient with serum sickness. *a*, Cell with reticular type nucleus. *b*, Condensation of nucleus. *c*, Further condensation of nucleus and cytoplasm to close approximation of plasma cell.

DISCUSSION

These experiments show two phenomena of interest. There is an increase in a specific type of bone marrow reticulum cell following sensitization to an antigen. Second, anaphylactic shock initiates a morphologic cycle by which the reticular plasma cells evolve to plasma cells. We have noted the development of similarly striking plasmacytosis in the other reticulo-endothelial organs following sensitization and shock with bacterial and other antigens. In view of the evidence in the literature and our own experiments, it is highly suggestive that the transformation of the plasmaeytic reticulum cell to the Marshalko type

plasma cell is intimately associated with the production of antibody protein. It is consistent with recent findings (Dougherty and White, 1946, Dempsey and Wislocki, 1946) to presume that the basophilia of the early plasmacyte may be associated with heightened protein formation. In view of the needs of the organism at this time, antibody production might well be carried on in such active cells. Certain it is that the loss of volume is a most striking cellular change in the procession of stages from basophilic reticulum to small plasma cell. Yet, the impression is gained that stainable material in these preparations is not reduced. A loss of the fluid components of the cell is obvious. It would be hard to overlook, however, the possible relation of the antigen-antibody reaction to the permeability of the cell membrane in searching for a possible mechanism for these changes. If serum hyperglobulinemia is directly related to plasma cell development, it is likely that some of the cell shrinkage may be due directly to loss of protein elements in the form of globulin. Morphology reaches its limitations in this type of work and must be supplemented by other methods. Before a thorough understanding of this matter is to be had, we must know whether, in tissue culture, the cell changes under question are associated with the production of antibodies. In addition, the role of the various cell organelles in the reaction to anaphylactic shock must be worked out on a cytochemical basis.

Another aspect of the problem which must remain speculative until more detailed information is available is the nature of the stimulus furnished by anaphylactic shock, which brings about the sequence of cell transformations that produces Marshalko plasma cells from a much less differentiated type of cell. The spectacular operation of this cytomorphosis not only serves to illustrate the exquisite relation between physiologic changes and the ontogeny of cellular elements, but it also promises to serve as an experimental preparation for the determination of the relation of nuclear changes to cytoplasmic activity.

Markoff's work on serum sickness, as well as our case, serves to illustrate the clinical importance of the matter under discussion. It is apparently the exceptional case in which plasma cells are found in the peripheral blood, but the concomitant appearance of circulating reticular plasma cells indicates that the process in the bone marrow is essentially the same as in the bone marrows of experimental animals. It should be noted that in the rabbits, circulating plasma cells were not regularly found, and we may believe that some secondary factor in our clinical case brought the cells into the peripheral blood.

SUMMARY

1. An analysis of the literature provides ample evidence to link plasmacytosis to antibody production.
2. With *Str. viridans* and egg white as antigens, sensitization of rabbits was found to increase enormously the number of reticular plasma cells in the bone marrow.
3. Shocking the animals with the antigen initiated a cycle of nuclear and cytoplasmic condensation, visible in two hours and extending to four days, by which the reticular plasma cells are transformed to Marshalko type plasma cells,

4. In a case of human serum sickness, both reticular plasma cells and various stages of the plasma cell appeared in the peripheral blood.
5. It is suggested that this morphologic cycle is associated intimately with the production of antibodies.

HEMATOPOIESIS IN THE BONE MARROW OF RATS RECOVERING FROM NUTRITIONAL ANEMIA

CHRISTOPHER J. HAMRE, PH.D.
MINNEAPOLIS, MINN.

INTRODUCTION

THE present paper is a report on the results of studies of the hematopoietic activities found in the bone marrow of rats made anemic by being fed a diet composed of milk only and then caused to recover from the anemia by being fed copper and iron as supplements to the milk diet. Studies of the recovery of rats made anemic by this method have seldom included observations on changes in the number of leucocytes but have chiefly been concerned with the regeneration of hemoglobin and erythrocytes and with the agents which induce regeneration of those blood elements. The level of hemoglobin and the number of erythrocytes of the circulating blood have been employed as indicators of the severity of the anemia produced by feeding the milk diet, and the rate and degree of regeneration of those hematologic elements have been used to measure the curative properties of substances added to the milk diet. Through the work of Hart, Steenbock, and Elvehjem and co-workers,¹⁻⁵ Beard and Myers and associates,¹⁰⁻¹⁷ Mitchell and Miller,¹⁸ Hamre and Miller,^{19, 20} Smith and Otis,²¹ Stein and Lewis and co-workers,²²⁻²⁵ and others, it has been established that copper and iron when fed simultaneously in adequate quantities as supplements to the milk diet will cause recovery from the anemia.

Studies of the blood-forming organs of rats in nutritional anemia and of rats recovering from the anemia have been few in number. Von Haam and Beard²⁶ found the spleen of rats made anemic by being fed a diet of milk only to be small, pale, and soft. The spleens of the anemic animals possessed fewer and smaller follicles, a decreased perfollicular zone, and pulpar cells which showed signs of degeneration. Hamre and Miller¹⁹ also found the spleens of anemic rats to be small in size and to possess a decreased amount of white pulp tissue, the decrease in the extent of the tissue being due to a loss of the outer zone and part of the inner zone of the Malpighian corpuseles and of the outer portions of the periarterial white pulp. The red pulp was increased in area and included circulating mature red blood cells and normal reticular cells. There was no indication of cell multiplication in the spleens of the anemic animals. The latter authors also demonstrated that, during the recovery from the anemia following iron and copper therapy, the spleens of the animals became temporarily enlarged and mottled with grayish-white hematopoietic areas. When approximately normal values of the blood were restored, the spleens of the recovering animals decreased to normal size. The white pulp

Published with the permission of the Director of the Hawaii Agricultural Experiment Station as Technical Paper No. 152.

tissues were regenerated and restored to normal histologic appearance during the period of enlargement, and the normal appearance of the white pulp was retained when the spleens returned to normal size. Active erythropoietic tissue occupied the red pulp areas of the enlarged spleens, and in the early periods of recovery those areas included large numbers of hemocytoblasts while in the later periods of recovery the areas were composed largely of polychromatophilic normoblasts. The erythropoietic areas decreased in extent and disappeared in the later periods of recovery. In a later study Hamre and Miller²⁰ demonstrated that removal of the spleens of anemic animals did not prevent the recovery of hemoglobin and erythrocytes under copper and iron therapy. However, there were indications that the rate of recovery of the erythrocytes was slower for the splenectomized than for the nonsplenectomized animals.

The paper by Fitz-Hugh and associates,²⁷ as far as the present writer has been able to determine, is the only paper in the literature on the nutritional anemia of the rat which presents observations on some of the characteristics of the bone marrow of anemic animals and of animals recovering from the anemia. These authors made observations on the quantity of fatty and cellular tissue of the marrow and pointed out that the cellularity of the marrow of normal animals was greater than that of anemic animals. They also noted that the addition of curative agents to the milk diet caused an increase in the cellularity of the marrow of all of their treated animals. For animals fed iron alone as supplement to the milk diet, the hyperplasia of the marrow tissue persisted throughout a seventy-day period of therapy. The marrow of anemic animals fed iron and copper, or iron and sodium glutamate, became highly hyperplastic in the early stages of recovery but in the later stages became less cellular than the marrow of normal animals. Though the paper²⁷ did indicate that gross microscopic changes of the bone marrow of anemic animals did follow therapy, it did not describe the cytology of the marrow tissues or point out the nature of the hematopoietic response to therapy.

Because of the marked hematopoietic response of the spleen and the rapid restoration of normal blood values which followed the feeding of therapeutic agents, the present writer assumed that the bone marrow of anemic animals similarly would exhibit a sharp hematopoietic response to therapy. Preliminary studies of the bone marrow of animals killed at daily intervals during recovery from anemia were carried out, and, though an increase in the cellularity of the marrow was found, the cytologic characters noted indicated that only hematopoiesis of the homoplastic type occurred. However, the observations of Hamre and Miller²⁰ that marked increases of normoblasts and leucocytes of the circulating blood occurred on the second and the fifth or sixth day of therapy suggested that a marked change of hematopoiesis of the bone marrow might occur during the first day of feeding of the iron and copper supplements. Study of the bone marrow of rats killed at hourly intervals during the first two days of supplement feeding did show a marked hematopoietic response to the therapy. The present paper describes the hematologic changes found to occur in the bone marrow and the blood of anemic animals during the first forty-eight hours of the recovery period.

MATERIALS AND METHODS

Sixty animals divided into three groups of twenty each were observed in these studies. Though the three groups of animals were placed on experiment at different times, to establish identical conditions for study, all animals were managed in the same manner. All animals were made anemic by the method outlined by Elvehjem and Kemmerer,²⁸ that is, at the age of 21 days they were weaned and placed on a diet of cow's milk. The milk was obtained at the University Farm and was collected directly into glass bottles and fed to the animals in glass dishes. The animals were kept in individual galvanized iron wire cages. When the hemoglobin value had decreased to 3.5 Gm. or less, per 100 c.c. blood, the animals were given iron and copper as supplements to the milk. Eighteen of the animals of the first group were fed the iron and copper supplements after 28 to 32 days on the milk diet while the remaining two animals of the group were kept on the milk diet for 44 days. The animals of the second and third groups, though they possessed satisfactorily low hemoglobin values after 28 days on the milk diet, were continued on the deficient diet for 36 to 54 days in the hope that the hemoglobin and erythrocyte values would be further reduced and a more severe anemia established. Though the animals continued on the milk diet for the longer periods did become progressively weaker, only slight decrease of hemoglobin and erythrocyte values occurred for some but not all animals. Each animal fed the copper and iron supplements received a single dose of the curative agents unless they were continued under observation for more than 24 hours when they were given a second dose of the supplements at the beginning of the second 24-hour period. A single dose of the curative agents consisted of 0.5 mg. iron for all individuals and copper fed at the rate of 0.003 mg. per gram body weight. The iron was supplied as ferric chloride ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$) and the copper as cupric sulfate ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$). The copper and iron content of the various solutions used were checked by the colorimetric method.

The first group of twenty animals was employed as a part of a preliminary experiment to determine approximately at what time during the early stages of recovery critical or significant phases of hematopoiesis might occur. Because of the erythropoietic function of the spleen during recovery, it was decided that anemic animals with large, actively erythropoietic spleens should not be used in this study. Each animal, therefore, was subjected to laparotomy and the size and appearance of the spleen were noted. All animals were used in the experiment because the spleens were small or medium sized and none possessed grayish-white erythropoietic areas. Two of the animals, to serve as controls, were killed without having received copper and iron supplements. Seventeen of the animals were fed iron and copper and one of these was killed at each of the following hours after copper and iron feeding: 2, 3, 5, 7, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30, 36, and 48 hours. The twentieth animal of this group was bled hourly from the fourteenth to the twenty-eighth hour after feeding to provide hourly blood values.

Since none of the animals of the first group possessed large and actively erythropoietic spleens and laparotomy introduced a complicating factor into the experiments, none of the animals of the second and third groups were subjected to exploratory operation. Five of the animals of these groups were killed as anemic control animals. Since the animal of the first group killed at 22 hours after iron and copper feeding possessed a bone marrow showing a particularly sharp response to therapy, the animals of the second and third groups and which received iron and copper, were killed at some hour between 10 and 48 hours after supplement feeding.

Hemoglobin, erythrocyte, leucocyte, and platelet values were determined for all control animals and for all treated animals at the time they were given their first dose of copper and iron and again at the time they were killed. All blood samples were obtained from the rat's tail by the usual methods. Hemoglobin values were determined by the acid hematin method employing a Klett-Summerson photoelectric colorimeter. The erythrocyte and leucocyte counts were made by the usual methods and the platelet counts by the method of Reese and Ecker. At the time blood samples were taken for blood values, blood smears were also prepared. The blood smears were stained with Wright's stain and Giemsa stain. At the time the animals were killed, the femur, humerus, vertebrae of the base of the tail,

and vertebrae from the middle of the free portion of the tail were cleaned of muscles and connective tissue and fixed in Helly's Zenker-formol fixative. The marrow tissue of one femur was removed and a portion used to prepare smears and imprints and the remainder fixed for sectioning. The smears of the bone marrow were stained with Wright's stain followed by Giemsa stain. Entire bones and the marrow removed from the femur fixed for histologic sections were embedded in celloidin, decalcified, sectioned, and stained in hematoxylin eosin, hematoxylin-eosin-azure II, or Dominici's toluidine blue-eosin-orange G stain.

OBSERVATIONS AND RESULTS

The results of this investigation will be presented in two parts, the first dealing with the values for the hemoglobin and blood cells of anemic animals and animals given iron and copper supplements and the second with the histology of the bone marrow of anemic and treated animals. Observations on the values of the blood elements are presented for the purpose of indicating the characteristics of the anemia investigated in this study and because the changes of the values of the blood elements which follow treatment with copper and iron help explain the histologic changes found in the bone marrow. The relation of the hematologic conditions observed to the controversial problems and theories of hematopoiesis will be presented in the discussion which follows this section of the paper.

The anemic animals were physically weak and inactive and many of the animals, often in spite of high platelet counts, showed a tendency toward failure of blood coagulation, the bleeding from the tail after taking blood samples being difficult to control. The average values and range of values of the blood elements of the anemic animals are summarized in Table I. The range of values recorded for hemoglobin and erythrocytes and the presence of normoblasts in the blood smears indicate that the anemia for all animals was a severe one. Though the total number of leucocytes was reduced below normal, the absolute values given for the various types of leucocytes show that the differential leucocyte count was approximately normal and the lymphocyte the predominant leucocyte type of the blood smear. The platelets, as shown by the range of values listed in Table I, were extremely variable in number for our anemic animals.

The anemia produced by feeding milk to the rats of this experiment was of the microcytic, hypochromic type. Anisocytosis was marked and the blood smears showed quite clearly that the greater number of erythrocytes was smaller than normal. An average of 4.5μ was obtained by employing a diffraction erythrocytometer for measuring the diameter of the erythrocytes of the blood smears of thirty-six of the anemic animals. Though there is no agreement in the published values for the diameter of the red cells of normal rats, the values of 5.7μ given by Kleiberger,²⁹ 6.3μ given by Scarborough,³⁰ and 6.8μ given by Gulliver and quoted by Ponder³¹ are all greater than the average diameter obtained for our animals. The erythrocytes of the blood smears were either strongly basophilic, polychromatophilic, or possessed a faintly stained narrow acidophilic margin. Basophilic stippling of the red cells was present and Jolly bodies were encountered quite frequently in the blood smears. Poikilocytosis was either absent or slight.

TABLE I. SUMMARY OF BLOOD VALUES OF ANEMIC RATS AND RATS AFTER COPPER AND IRON THERAPY

BLOOD ELEMENT	AVERAGE VALUES*		RANGE OF VALUES*	
	ANEMIC ANIMALS ON DAY KILLED AS CONTROLS OR FED COPPER AND IRON SUPPLEMENT	TREATED ANIMALS KILLED FROM 2 TO 48 HOURS AFTER FIRST FEEDING OF COPPER AND IRON	ANEMIC ANIMALS ON DAY KILLED AS CONTROLS OR FED COPPER AND IRON SUPPLEMENT	TREATED ANIMALS KILLED FROM 2 TO 48 HOURS AFTER FIRST FEEDING OF COPPER AND IRON
Hemoglobin in grams per 100 c.c. blood	2.8 (54)†	3.3 (46)‡	Less than 2.0 to 3.8 (59)	Less than 2.0 to 5.2 (50)
Erythrocytes in millions per c.mm. blood	2.05 (59)	2.22 (52)	1.16 to 2.92 (59)	1.29 to 3.41 (52)
Leucocytes in thousands per c.mm. blood	5.37 (57)	16.44 (50)	2.71 to 11.65 (57)	3.16 to 42.71 (50)
Platelets in thousands per c.mm. blood	409 (40)	433 (36)	96 to 814 (40)	80 to 926 (36)
Normoblasts in number per c.mm. blood	208 (57)	2121 (50)	0 to 2063 (57)	0 to 8426 (50)
Heterophile in number per c.mm. blood	2060 (57)	10,171 (50)	441 to 4943 (57)	1408 to 32,708 (50)
Eosinophiles in number per c.mm. blood	78 (57)	429 (50)	0 to 331 (57)	0 to 2431 (50)
Lymphocytes in number per c.mm. blood	3433 (57)	5359 (50)	1005 to 6156 (57)	1256 to 17,738 (50)

*Numbers in parentheses indicate the number of animals observed for each blood element.

†Five additional animals had less than 2.0 Gm. hemoglobin per 100 c.c. blood and, therefore, below the lowest calibration of the colorimeter. These animals were not included in the computation of the average value.

‡Four additional animals had less than 2.0 Gm. hemoglobin per 100 c.c. blood and, therefore, below the lowest calibration of the colorimeter. These animals were not included in the computation of the average value.

In this study the anemic animals given recovery treatment were killed a few hours after the initial copper and iron feeding and, therefore, did not show marked improvement in general physical condition. However, the animals continued to the end of the 48-hour observation period were more active than before receiving copper and iron. The anisocytosis did not disappear and in some instances was more marked after therapy than before. Likewise, the microcytosis was continued, the average diameter of the erythrocytes of thirty-six treated animals being 4.5μ . The basophilic erythrocytes in some instances were increased in number and in general the hypochromasia continued unchanged after therapy. From these observations it is apparent that for the period of the first 48 hours after the initial copper and iron feeding, the hypochromic and microcytic character of the anemia was continued and was not markedly altered.

The values for the hemoglobin and blood cells of the animals fed copper and iron are summarized in Table I. Though the average values and range of values presented in the table are for all animals fed the curative substances and does not take into consideration the fact that the animals were killed at various times after supplement feeding, they do indicate the character of the response to therapy. Slight increases in value are indicated for hemoglobin, erythrocytes, and platelets, while marked increases in number are shown for normoblasts and leucocytes. The great increase in number of white blood cells is shown to be due primarily to an increase in number of heterophile leucocytes.

Though lymphocytes were increased over their values for untreated anemic animals, their increase in number was small when compared to the increase in number of heterophile leucocytes. As a result the differential leucocyte count was altered, the heterophile becoming the predominant leucocyte type after treatment. The marked increase in number of normoblasts, eosinophiles, and heterophiles shows that the first response to copper and iron feeding is myeloid in nature and characterized by a discharge of those cells into the circulating blood by the bone marrow.

Examination of the hemoglobin and blood cell values for animals killed at different hours after the initial feeding of copper and iron shows that a latent period of no regular gain immediately follows the feeding. It also shows that the latent period continues to 26 hours for hemoglobin and 28 hours for erythrocytes, while for normoblasts and leucocytes it continues only to 12 hours after feeding. The duration of the latent period is shown particularly well by the gain or loss in values shown in the graphs of Figs. 1 and 2. Since the platelets did not show a definite regular response to therapy, their changes in values were not graphed and included in the illustrations.

Though Krumbhaar,³² Wintrobe,³³ and others state that due to an increase in number of neutrophils, a postoperative leucocytosis is found to occur, the values for leucocytes of our animals subjected to laparotomy do not differ significantly from the values of animals not subjected to operation. We have concluded that the change in numbers of normoblasts and leucocytes of the circulating blood of our animals was due to the copper and iron feeding. We have also concluded that the increase in number of those cells was due to their discharge by the bone marrow and that they were discharged during the period of high and low values extending through the period between 12 to 26 hours after copper and iron feeding. That period we regard to be a critical period of response to therapy and, as will be described, is accompanied by critical changes of hematopoiesis in the bone marrow.

The bones whose marrow tissues were observed for histologic changes in this investigation, on the basis of position in the body, were of two types, outlying or distal bones represented by the caudal vertebrae and central bones represented by the femur and the humerus. Huggins and Blocksom³⁴ have pointed out that in the rat the marrow of the outlying bones is characteristically of the hematopoietically inactive yellow type while that of the central bones is of the hematopoietically active red type. We assumed that by including representative bones of the two types we would be presented the opportunity of noting the reaction of both yellow and red marrow to anemia and to therapy. The marrow tissues of the two types of bones were found to be dissimilar both in the anemic state and after therapy and, therefore, require separate consideration and description.

Longitudinal sections of vertebrae from two portions of the tail, namely, vertebrae of the middle of the free portion of the tail and vertebrae immediately following the sacral vertebrae at the base of the tail, were prepared for histologic study of the marrow. The marrow tissue of the vertebrae of the two regions of the tail presented some points of difference. The marrow of the

distal caudal vertebrae, except for a few islands of hematopoietic tissue in the epiphyses and metaphyses, was of the yellow variety throughout. The marrow of these vertebrae resembled that described by Huggins and Bloksom²¹ for normal adult rats, and it is apparent that in our animals the existence of a severe anemia had not produced active hematopoietic tissue in these vertebrae. The marrow of the distal caudal vertebrae showed no histologic changes in response to copper and iron therapy. The first caudal vertebra of anemic

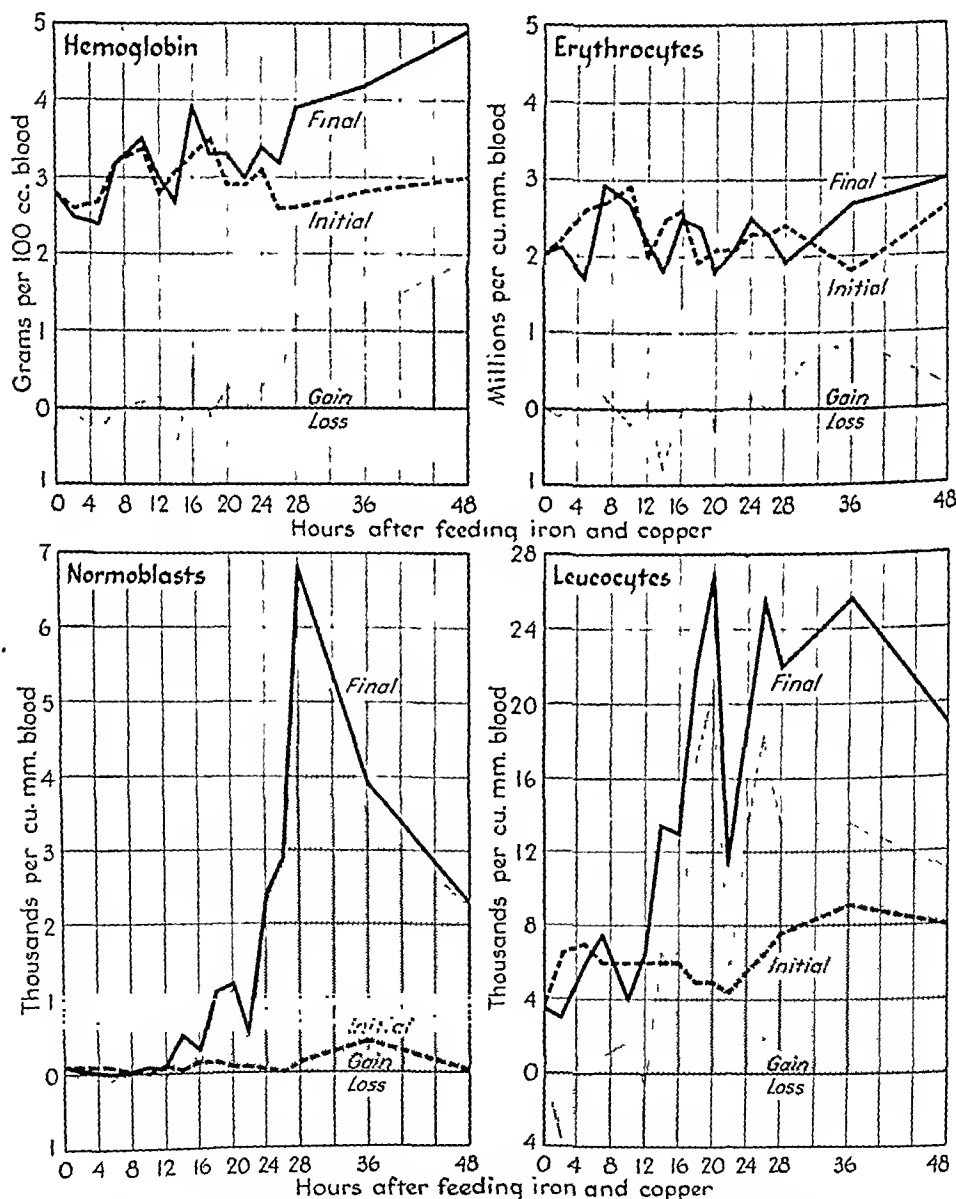

Fig. 1.—Effect on hemoglobin erythrocytes, normoblasts, and leucocytes of feeding a total of 0.5 mg. iron and 0.003 mg. copper per gram body weight.

animals possessed fairly abundant red marrow in both epiphysis and centrum. Fat cells were present in the marrow and were most abundant toward the posterior end of the vertebra. The first caudal vertebra possessed more red marrow and less yellow marrow than the second and third caudal vertebrae, and the third vertebra possessed less red and more yellow marrow than the second vertebra. The third caudal vertebra, therefore, possessed more yellow marrow than red marrow. It should be noted that for the second and third

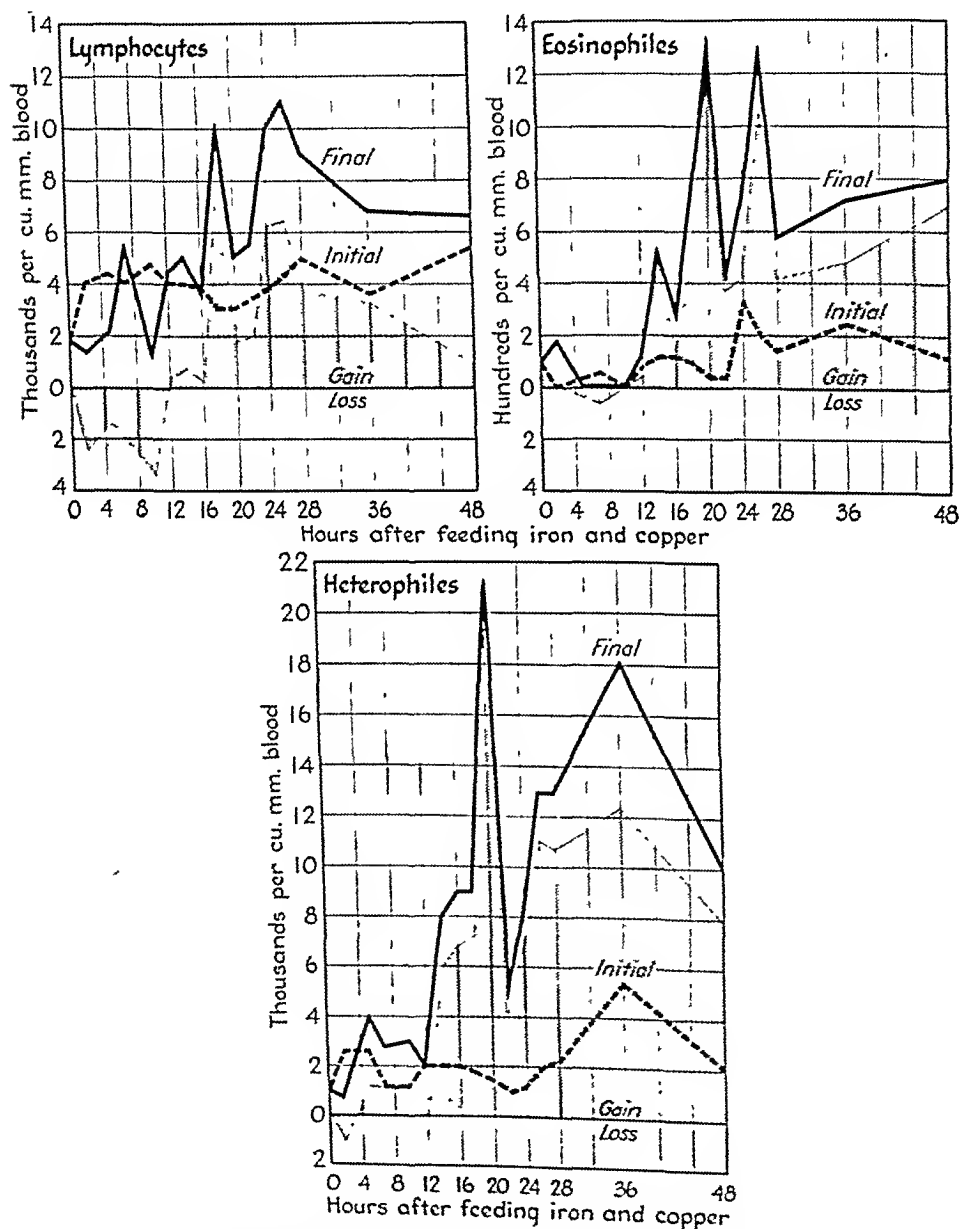

Fig. 2.—Effect on lymphocytes, eosinophiles, and heterophiles of feeding a total of 0.5 mg. iron and 0.003 mg. copper per gram body weight.

caudal vertebrae the red marrow was best developed and most active at the anterior end. The decrease in red marrow and increase in yellow marrow from the first to the third caudal vertebrae were anticipated because the first vertebra is essentially a central type of bone while the third caudal vertebra is essentially an outlying type of bone. Though histologic changes were found to occur in the red marrow of the first and to some extent in the second caudal vertebrae after therapy, the changes were not as extensive or as marked, though of the same nature, as those found to occur in the femur and humerus. For that reason further description of the marrow of the caudal vertebrae will not be given. Our observations indicate that the severe dietary anemia of our study did not cause the extension of red marrow into typical yellow marrow areas and that typical yellow marrow does not, for the 48-hour period of observation of this study, respond to copper and iron therapy.

The sections of the marrow removed from the femur before being placed in the fixative when stained with hematoxylin-eosin-azure II provided the best material for the identification and study of the various stages of hematopoiesis. However, the marrow removed from the marrow cavity before fixation did not include the marrow tissues at the periphery and epiphyseal ends of the marrow cavity and did not provide a complete picture of the marrow tissue. Longitudinal sections of the entire femur and also of the humerus, though not as sharply stained with the hematoxylin-eosin-azure II, provided excellent material for study of the cytology of red marrow as well as for the extent of the red marrow tissues. The marrow tissue of the femur and humerus, both in the anemic state and after therapy, were essentially similar as far as hematopoietic activity was concerned and were used to supplement each other in this study. The descriptions of the cytologic changes of the marrow to be given are based largely on the longitudinal sections of the entire femur and of the marrow removed from the femur before fixation. The smears and imprints were very useful in identifying hematopoietic cells and were used to supplement the sectioned material.

The histology and cytology of typical femur marrow of anemic rats of this experiment are illustrated in Fig. 3. It should be noted that the marrow tissue of anemic animals was of the hyperplastic red type throughout the entire extent of the femur and the humerus. Fat cells were very few in number and were most commonly found, scattered singly or in groups of a few cells, in the tissue at the periphery of the marrow of the central cavity and in the marrow of the epiphyses. The venous sinuses were prominent and well defined and the reticular lining cells forming their walls were continuous and distinct. There was no indication of a discontinuous wall of the venous sinuses in any of our sections in which the tissues were satisfactorily stained. The inter-sinusoidal tissue, or parenchyma, was sharply limited by the reticulo-endothelial walls of the venous sinuses and toward the central portion of the tissue were found the arteries and arterioles supplying it. The parenchymatous tissue was fairly cellular and compact though open enough to permit easy identification and study of the reticular cells forming its framework. Some of the reticular cells were in the process of mitosis and others, as shown by the lack

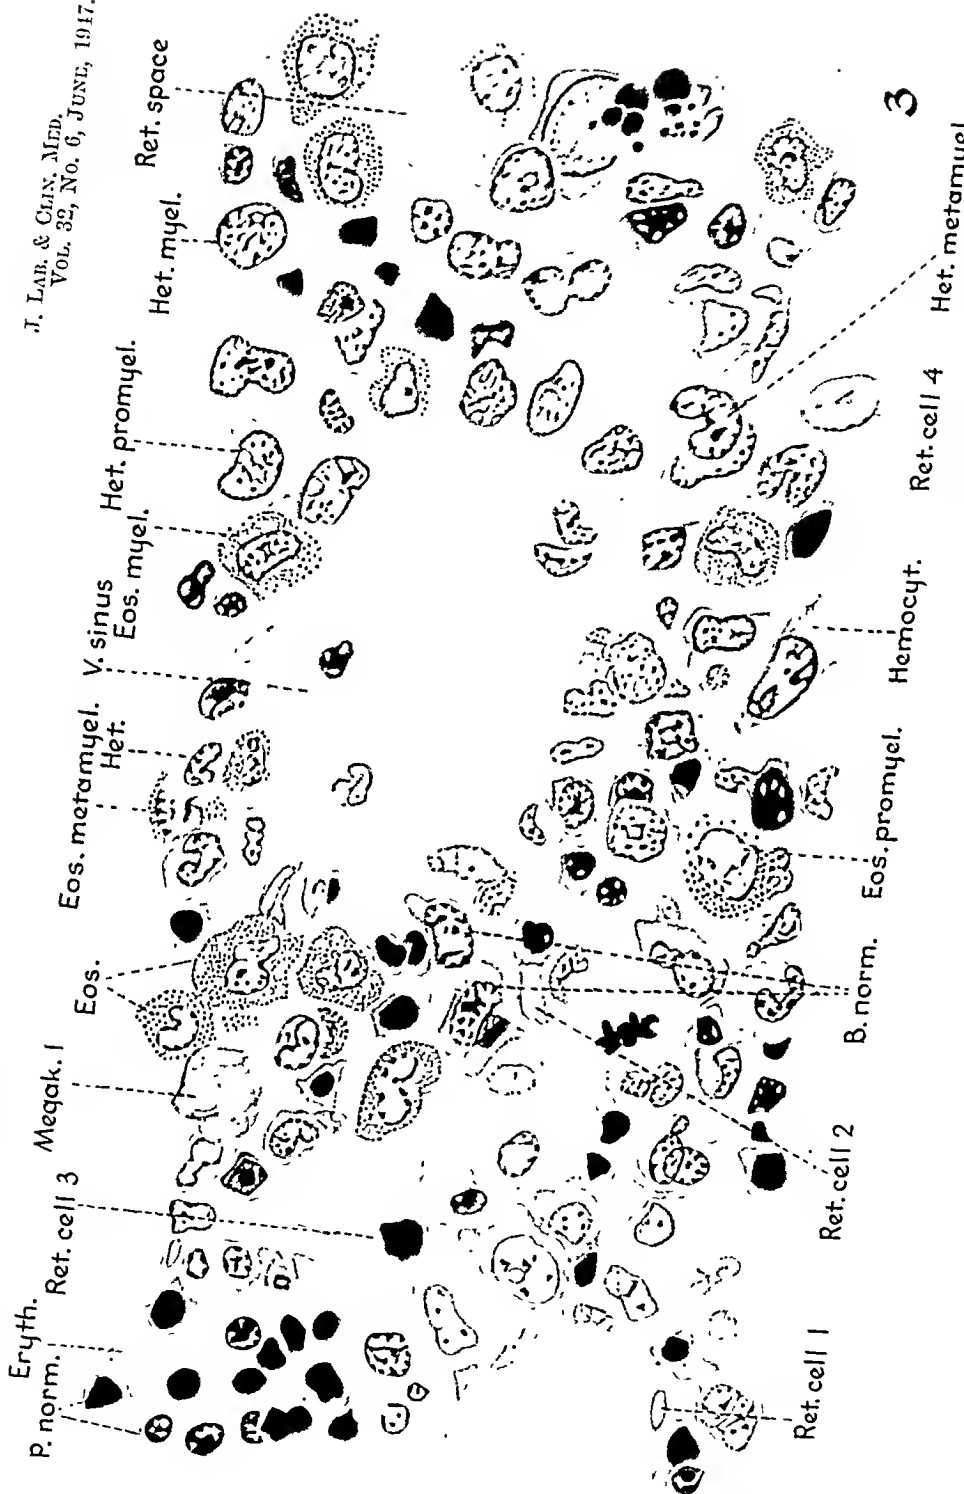

Figs. 3, 4, and 5.

Sections of marrow of femur of untreated anemic rat (Fig. 3), anemic rat killed 22 hours after receiving 0.5 mg. iron and 0.22 mg. copper (Fig. 4), and anemic rat killed 15 hours after receiving 0.5 mg. iron and 0.26 mg. copper (Fig. 5).

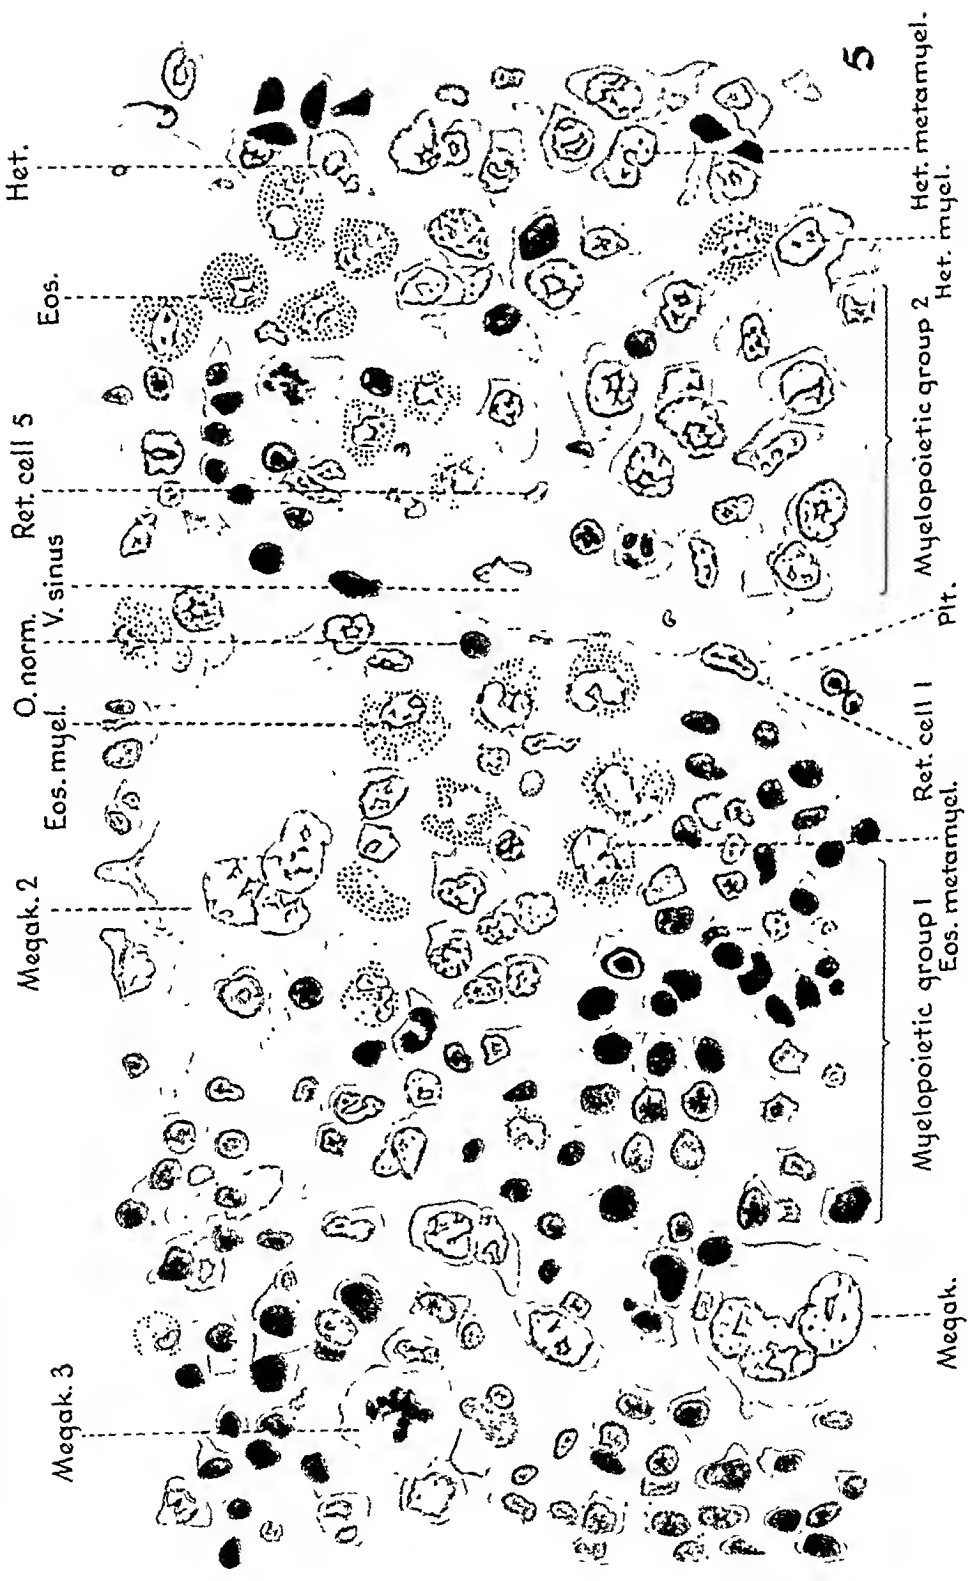

All tissues fixed in Zenker-formol and stained in hematoxylin-eosin-azure. Camera lucida drawings, X1100.

In all cases the abbreviations have the following meaning: *B.*, Basophil; *P.*, polychromatophil; *Pl.*, plasma; *O.*, orthochromatophil; *Eos.*, eosinophil; *Eryth.*, erythrocyte; *Hemacut.*, hemocytoblast; *Hel.*, heterophil; *Meak.*, megakaryocyte; *myel.*, myelocyte; *metamyel.*, metamyelocyte; *norm.*, normoblast; *Plt.*, platelet; *Promor.*, promonoblast; *Ret.*, reticular; *V.*, venous.

Eosinophil (*Eos.*, 4, Fig. 4) and polychromatophil normoblast (*P. norm.*, 4, Fig. 4) entering venous sinus; pronormoblast in mitosis (*Promor.*, 4, Fig. 4); megakaryocytes in mitosis (*Meak.*, 4, Fig. 5), showing platelet formation (*Meak.*, 2, Fig. 5), and in degeneration (*Meak.*, 1, Fig. 3); group of normoblasts in hemopoietic development (*Myelopoeitic group* 4, Fig. 5) and heterophiles in hemopoietic formation (*Myelopoeitic group* 2, Fig. 5); reticular cells lining venous sinuses (*Ret. cell* 1, Figs. 3, 4, and 5), reticular cells of stroma (*Ret. cell* 2, Figs. 3 and 4), stroma reticular cell in mitosis (*Ret. cell* 3, Fig. 3), reticular cell transforming into hemocytoblast (*Ret. cell* 3, Fig. 3), and stroma reticular cell bordering on lining cell of venous sinus (*Ret. cell* 5, Fig. 5).

of long processes, basophilia of the cytoplasm, and nucleus with coarse chromatin and distinct chromatin nucleoli, were in the process of changing into hemocytoblasts. The reticular cells at the margin of the intersinusoidal tissue sent processes to the reticular lining cells of the venous sinuses and contributed to the formation of the wall of those vessels. Other reticular cells sent their processes to the walls of the arterioles and arteries located in the stroma. The hematopoietic tissues located in the reticular spaces of the stroma were divided into separate and fairly well-defined groups of differentiating erythrocytes, eosinophiles, and heterophiles. The tendency of the hematopoietic cells to separate into groups of similar cells was best seen in areas of longitudinal sections through the intervacular tissue and the neighboring venous sinuses.

The primary hematopoietic process of the bone marrow of anemic animals was of the homoplastic type. Orthochromatophile and polychromatophile normoblasts, the latter the most numerous, formed the greater part of the nests of erythropoietic cells. It should be emphasized that the cytoplasm of the orthochromatophile normoblasts, as shown in Fig. was not acidophilic as in normal bone marrow but more or less strongly basophilic and stained with the azure stain instead of the eosin stain. They were readily identified, however, by their deeply stained pyknotic nuclei. The basophile character of the cytoplasm of the orthochromatophile normoblasts of the marrow of our anemic animals was expected because many of the erythrocytes of the circulating blood lacked hemoglobin and possessed basophilic or faintly acidophilic cytoplasm. The polychromatophile normoblasts likewise were identified by their nuclei, of coarse, radially arranged and deeply stained chromatin masses and not by the cytoplasm which was basophilic rather than polychromatophilic. Basophile normoblasts were few in number. They were characterized by deeply stained basophilic cytoplasm and a nucleus possessing fairly large chromatin nucleoli and coarse chromatin granules placed on the inner surface of the nuclear membrane. Pronormoblasts were encountered fairly frequently in the nests of erythropoietic cells and differed from the basophile normoblasts in possessing more prominent chromatin nucleoli, finer chromatin granules on the nuclear membrane, and a more irregular cell outline. Mitoses of the erythropoietic cells were very infrequent and it appears that the low erythrocyte count of the anemic animals was the result of arrested cell multiplication and differentiation.

Nests of eosinophilic cells, being almost as numerous as nests of heterophilic cells, were more numerous than the number of eosinophile leucocytes of the circulating blood indicated should have been present. The granules of the developing eosinophilic cells were large and brilliantly stained by the eosin dye. Mature eosinophiles were identified by the presence of an abundance of eosinophilic granules, a faintly acidophilic cytoplasm, and a nucleus more or less deeply indented to form two nuclear lobes. The chromatin of the nucleus of the eosinophiles included small and medium-sized granules in the interior and granules of irregular size placed on the inner surface of the nuclear membrane. The eosinophile metamyelocytes also possessed numerous granules, faintly acidophilic cytoplasm, and a nucleus only slightly indented or perforated at

the center or toward one side. Formation of the eosinophile metamyelocytes from myelocytes was either by indentation or perforation of the nucleus, the latter method of formation occurring most frequently. The eosinophile myelocytes formed the most common cell of the eosinophile nests. They possessed a slightly basophilic cytoplasm, fairly numerous granules, and a spherical nucleus with chromatin nucleoli and numerous fairly fine chromatin granules on the nuclear membrane. Eosinophile promyelocytes, though rarely encountered, were readily identified by their basophilic cytoplasm, reduced number of granules, and a large spherical nucleus. The chromatin of the nucleus of the promyelocyte included fairly large chromatin nucleoli and fine chromatin granules in the interior and on the nuclear membrane. Hemocytoblasts, or myeloblasts, of the eosinophile nests were not numerous but were more numerous than the promyelocytes. They resembled the pronormoblast in shape, basophilic staining of the cytoplasm and in the presence of large irregular chromatin nucleoli in the nucleus. They differed from the pronormoblasts in that the chromatin granules on the nuclear membrane were finer and more numerous than those found on the membrane of the pronormoblast. Mitoses of the myelocytes were very infrequent, and it appears that for the eosinophile series, as for the erythrocyte series, cell multiplication and differentiation was suppressed by the anemia.

The cells of the heterophile series of leucocytes also occurred in irregular nests but were the most difficult to identify because the cytoplasm of even the most mature cells of the series was faintly basophilic and because specific granules were not stained or when stained were so small as to be difficult to see. However, it was possible to identify the various stages of differentiation of the heterophiles by comparing their nuclei with the nuclei of the various differentiation stages of the eosinophiles. Since the structural features of the nuclei of the differentiation stages of the heterophiles are like those of the eosinophiles, descriptions of them will not be repeated here. The heterophile promyelocytes were very difficult to identify because of their close resemblance to hemocytoblasts and because of the absence of specific granules. Myelocytes were fairly numerous and differentiation into metamyelocytes was by nuclear perforation or indentation and, as for eosinophiles, most frequently by the former method. Late heterophile metamyelocytes possessed a slender bandlike nucleus while mature heterophiles possessed two or more nuclear lobes. Mitoses of the myelocytes of this series were very infrequent and multiplication and differentiation of the cells of the heterophile series were also suppressed by the anemia.

Basophiles, or mast cells, were encountered very infrequently in the marrow of any of our animals. Plasma cells were found in the marrow of our anemic animals and were usually irregularly distributed through the tissue. Large-sized heterophiles and eosinophiles, most frequently encountered in the myelocyte and metamyelocyte stages, were found in the marrow of the untreated animals. Megakaryocytes showing platelet formation were not numerous. Naked nuclei of degenerating megakaryocytes were also present. An occasional megakaryocyte

was phagocytic, the phagocytosed cells most frequently being normoblasts readily identified by their small, spherical pyknotic nuclei.

The histologic and cytologic changes occurring in the marrow of anemic animals following the feeding of copper and iron supplements can best be described from marrows which had reached the point of greatest response to the therapy. One of the reactions to therapy was the appearance of mitoses in the cells of erythrocyte, eosinophile, and heterophile series. A second and unusual reaction to the therapy was the appearance of large numbers of pronormoblasts and heteroplastic erythropoiesis. The characteristics of a bone marrow showing that reaction in a high degree of development is illustrated in Fig. 4. The marrow illustrated was from an animal killed 22 hours after supplement feeding. Other marrows, namely, of individuals killed at 18, 20, 24, and 26 hours after feeding, showed approximately the same degree of development of heteroplastic erythropoiesis. The occurrence of well-developed erythropoiesis of that type for that fairly long period of time can be accounted for by individual variation in response to therapeutic treatment. The variation observed can be correlated with a similar variation in the values of normoblasts and leucocytes of the circulating blood shown for the same period of time in the graphs of Figs. 1 and 2. It should be noted that the marrow of other animals killed during this period of time also showed heteroplastic erythropoiesis but that the heteroplastic tissue did not occupy as great an area of the marrow.

The marrow at the height of response to therapy was characterized by greater cellularity and compact appearance of the intersinusoidal parenchyma. Venous sinuses, as for anemic animals, were well developed and prominent and their walls well defined. Arteries were located in the central portion of the intersinusoidal tissue area, and in general the vascular system and the intersinusoidal stroma tissue were the same as those found in the marrow of anemic animals. The intersinusoidal hematopoietic tissues were characterized by the presence in the central portion of the area and, therefore, surrounding the arteries and arterioles of a large number of pronormoblasts. Many of the pronormoblasts were in mitosis or were in preparation for mitosis. To either side of the mass of pronormoblasts, between them and the reticular lining cells of the wall of the venous sinuses, were found megakaryocytes and groups of erythrocytes, eosinophiles, and heterophiles in the later stages of differentiation. It was clearly evident in many preparations that the cells of this region were compressed by the new growth occurring in the central region of the intersinusoidal area. Numerous instances of normoblasts and granulocytes passing through the wall of reticular lining cells into the sinuses were found in these preparations. The constricted character of the cells passing through the membrane emphasizes the fact, also readily seen in the sections, that the reticulo-endothelial wall of the venous sinuses is a continuous one and that cells pass between the margins of the reticular lining cells. We have concluded that growth pressure within the intersinusoidal areas of our material assists in the migration of normoblasts from the intersinusoidal tissue into the venous sinuses.

The marrows of animals killed at earlier hours after feeding of copper and iron were studied in an effort to determine the origin of the pronormoblasts

which appear in such large numbers during the period of 18 to 26 hours after supplement feeding. It should be emphasized again that the marrow of anemic animals was hyperplastic but that cell multiplication and differentiation was depressed. It should also be pointed out that the vascular system of the marrow of anemic animals, of animals killed a few hours after supplement feeding, and of animals killed at the highest point of heteroplastic hematopoiesis were identical. The pronormoblasts appeared in the intersinusoidal areas and not in the vascular channels. It was noted earlier that instances of reticular cells of the intersinusoidal areas transforming into hemocyto blasts were found in our preparations of the marrow of anemic animals. Instances of such transformation were also found in the marrow of animals killed a few hours after therapy but instances of transformation were not very numerous. Transformation of reticular cells into hemocyto blasts does not satisfactorily account for the formation of such large numbers of hemocyto blasts. However, marrows of animals killed at 8 to 14 hours show many of the hemocyto blasts and pronormoblasts present to be in mitosis, and it appears that the greater number of pronormoblasts were formed in situ by multiplication of those cells and to a lesser degree by transformation of reticular cells into hemocyto blasts.

The marrows of animals killed at 36 and 48 hours after feeding of the iron and copper supplements illustrated in Fig. 5, show the usual arrangement of the venous sinuses and the intersinusoidal tissues. However, pronormoblasts were present in small numbers only, and it is evident that the heteroplastic erythropoiesis had disappeared as the result of the transformation of the pronormoblasts into the later erythropoietic stages. As a result, homoplastic hemopoiesis had been restored. Polychromatophilic and orthochromatophilic normoblasts, many of the former in mitosis, were very numerous. When the marrow of anemic animals and animals killed 48 hours after therapy were compared, it was found that the erythropoietic tissues were more extensive in the latter than in the former marrows. Nests of eosinophiles and heterophiles in homoplastic development were also present. Small megakaryocytes were fairly numerous and large well-developed megakaryocytes showed active platelet formation. Plasma cells and large eosinophiles and heterophiles were present but few in number. All features of the marrow of animals killed after 36 and 48 hours point to a normal condition of very active homoplastic blood cell formation.

DISCUSSION

The present study on dietary anemia of the rat produced by feeding milk alone confirms earlier work in showing that regeneration of the blood is initiated by the addition of copper and iron to the diet. It supports the work of Hamre and Miller^{19, 20} on the spleen and Fitz-Hugh and associates²⁷ on the bone marrow, in showing that the blood-forming organs respond to copper and iron therapy by increased hematopoietic activity. It further shows that the increased cellularity of the bone marrow of recovering anemic rats fed copper and iron noted but not identified by Fitz-Hugh and associates was due to an increase of homoplastic hematopoietic tissue. The material of this study definitely shows that accelerated homoplastic erythropoiesis is established as early as 36

hours after the initial copper and iron administration. It also shows that the first hematopoietic response to copper and iron therapy is the development of heteroplastic erythropoiesis. The heteroplastic erythropoiesis reaches its highest state of development some time during the period of 18 to 26 hours after adding copper and iron to the milk diet. The early heteroplastic erythropoiesis supplies increased erythropoietic tissue for the homoplastic erythropoiesis established 36 to 48 hours after the supplement feeding.

That the bone marrow of anemic animals does respond rapidly and strongly to effective therapeutic agents has also been indicated by other investigators. Doan and co-workers³⁵ state that the hematopoietic response of the hypoplastic marrow of the radius and the ulna of starved pigeons occurs only 18 hours after feeding is resumed. At that time differentiation of new fat cells begins and signs of reactivation of erythropoiesis appear. They point out that by 50 hours after feeding a normal appearance of the marrow has been established. Jordan and Johnson³⁶ also investigated the radial marrow of starved pigeons and state that at 28 hours after feeding is resumed hematopoiesis is established and that after that time the only feature of importance respecting hematopoiesis is that it becomes more intense and widespread. The work of McDonald³⁷ on the hypoplastic marrow of starved pigeons agrees with the observations of the previously mentioned two groups of investigators as far as the time of appearance of increased erythropoietic activity is concerned. Kandel and LeRoy³⁸ have indicated that in pernicious anemia in man fourteen and a half hours after liver therapy, the megaloblastic character of the sternal marrow has largely disappeared and has been replaced by an increased amount of normoblastic tissue. Bock and Malamos³⁹ reporting on their own observations and quoting observations of other European workers also point out that there is a rapid transformation of the marrow of patients with pernicious anemia after liver treatment and state that at 48 hours after first treatment megaloblastic cells are difficult to find while the early stages of the erythro-normoblastic type of cells are very numerous. It is obvious that the initial response of the bone marrow of the patients examined by the last group of authors occurred at some earlier hour of the first two days of recovery. Other papers pointing to the time of response of the bone marrow of animals to therapeutic treatment may exist in the literature on anemia but those cited previously in this paper support our view that a "critical period" of erythropoiesis occurs during the first few hours after effective therapy of anemia. For our anemic rats the critical period of recovery extended from 18 to 26 hours after the initial feeding of copper and iron and was characterized by a high degree of development of heteroplastic erythropoiesis. The fact that the height of heteroplastic erythropoiesis did not occur at some one hour of that period for all animals can be explained by the commonly accepted fact of existence of individual differences in the state of a disease and individual differences in reaction to therapy.

The studies of the changes of the blood values of rats recovering from anemia carried out in this investigation show that increases of values for normoblasts, eosinophiles, and heterophiles occur during a period of time which coincides with the critical period of hematopoiesis of the marrow. This period

for those blood cells extends from 12 to 26 hours after therapy. The coinciding of the periods of change of blood values and of the histology of the bone marrow suggest that the two are related and our material shows that the development of heteroplastic erythropoietic tissue is accompanied by a discharge of those blood cells into the venous sinuses. Hamre and Miller,³⁰ in studying the regeneration of the blood elements of anemic rats following copper and iron feeding, point out that for normoblasts and total number of leucocytes, chiefly heterophiles, the highest values occur on the second and the fifth or sixth day of recovery. Our material suggests that the high values for the second day are the result of the development of heteroplastic erythropoietic tissue in the marrow and the coincident discharge of cells present at the time treatment was begun. We suggest that the second period of high values occurring on the fifth or sixth day of recovery may mark the beginning discharge of a new generation of cells produced from the heteroplastic tissue of the critical period of hematopoiesis. Investigation of the marrow of animals in the second to the fifth day of recovery is needed to establish the significance of the second period of high values of normoblasts and leucocytes.

The marrows of the animals of this investigation, since they possessed large quantities of heteroplastic erythropoietic tissue, form material which bears on the controversial problem of the place within the marrow in which erythrocytes originate and differentiate. The literature bearing on this problem has been reviewed by Doan and co-workers³⁵ and Sabin and Miller,⁴⁰ and a review of the literature will not be presented here. Two views have been advanced in the literature on hematopoiesis, the first view that granulocytes develop extravascularly while erythrocytes develop intravascularly and the second view that both granulocytes and erythrocytes develop extravascularly. Differences of opinion on the place of differentiation of blood-cells in the bone marrow, therefore, center primarily about the place of differentiation of erythrocytes; it should be noted that the differences of opinion apply to erythropoiesis in the bone marrow of adult animals since the work of recent authors, Maximow⁴¹ and Bloom and Bartelmez⁴² on erythropoiesis in mammalian and human embryos and Dantchakoff⁴³ and Sabin⁴⁴ on avian embryos, agree in describing erythropoiesis as occurring intravascularly. The first view of erythropoiesis, therefore, holds that the embryonic type of intravascular erythropoiesis is continued in the marrow of the adult animal, while the second view holds that embryonic intravascular erythropoiesis during development is lost and is replaced by a new extravascular erythropoiesis in the bone marrow of the adult animal.

The more recent interpretations of the view that erythropoiesis occurs intravascularly in the marrow of adult animals is to a great extent based on the studies of Doan and co-workers³⁵ on the regeneration of the hypoplastic marrow of starved pigeons after normal feeding was resumed. They concluded that granulocytes are produced in the intervacular stroma but that erythrocytes are produced from the endothelium of hematopoietic capillaries, called intersinusoidal capillaries, originally described by Doan.⁴⁵ After maturing within the capillaries, the erythrocytes were described as being carried directly into the circulation and the capillaries as opening to the circulation

and temporarily ceasing erythropoiesis. Jordan and Johnson³⁵ and McDonald³⁷ after repeating the studies of these authors^{33, 45} doubt or deny the existence of intersinusoidal capillaries in the number or type described and suggest that many of the spaces so labeled are stromal reticular spaces. The latter authors^{36, 37} agree that granulocytes take origin in stromal spaces not open to the circulation. They also hold that cells of the erythrocyte series may mature within vascular channels but that the stem cells take origin from the extravascular stroma and then migrate into the vessels for maturation. McDonald also states that some of the erythropoietic cells of the vessels may take origin directly from the endothelium of the vessels without passing through the myeloblast stage. The recent literature on erythropoiesis in the bone marrow of birds indicates that differentiation, and possibly also origin, of erythrocytes occurs intravascularly.

Doan and co-workers³⁸ have also reported that intersinusoidal capillaries, similar to those described for the marrow of the pigeon, occur in the bone marrow of rabbits. They, therefore, reported erythropoiesis in the rabbit to be intravascular. Peabody⁴⁶ claimed to have seen intersinusoidal capillaries in the marrow of man and described erythropoiesis as occurring within them. However, the generally accepted view of hematopoiesis in the marrow of mammals, as noted by Bloom,⁴⁷ is that both leucopoiesis and erythropoiesis are extravascular. The generally accepted view of extravascular hematopoiesis is based largely on the clear and detailed descriptions of the process and the histology of the bone marrow of mammals given by Maximow.⁴⁸ The work of Drinker and associates⁴⁹ and Bunting⁵⁰ on the marrow of dogs, cats, and rabbits does not support the idea of the existence of intersinusoidal erythrocytogenic vessels but does support the view that in mammals granulocyte and erythrocyte formation is extravascular.

The review of recent investigations of hematopoiesis in the marrow of birds and mammals gives the impression that granulocytopoiesis is extravascular in both but that they may differ with respect to erythropoiesis. We do not deny the possibility of intravascular erythropoiesis in birds but on the basis of the evidences presented in the literature conclude that it may occur. On the other hand, we feel that evidences presented in the literature point to extravascular erythropoiesis in mammals. Our material on the marrow of the rat, in that it did not show erythrocytogenic vessels comparable to the so-called intersinusoidal capillaries or a change in the pattern of the vascular system during the initiation and development of erythropoiesis, supports that view. We feel that the appearance of new heteroplastic erythropoietic tissue in the parenchyma of the marrow, absence of masses of differentiating erythrocytes from the vascular channels, and the lack of hematopoietic activity on the part of the endothelial lining of the vessels lend strong support to the view that in adult mammals all erythropoiesis is extravascular and localized in the intervaseular areas of the marrow.

The heteroplastic erythropoietic marrows of the rats of this study, as pointed out in an earlier section of this paper, supply evidences on the manner of discharge of the inactive erythrocytes from the intersinusoidal areas into the

circulating blood. Explanations of the manner in which erythrocytes are so discharged would differ for instances of intravascular and extravascular erythropoiesis. In the former instance, as pointed out by Doan co-workers,³⁵ Jordan and Johnson,³⁶ and McDonald,³⁷ the erythrocytogenic vessels are continuous with the nonerythrocytogenic vessels and the mature erythrocytes are carried directly into the actively circulating blood of the latter. Explanations of the stimulation of release of the mature cells are not offered. In instances of extravascular erythropoiesis, the endothelial lining cells of the sinuses serve as barriers through which the red blood cells must pass to reach the circulating blood. It is on the possible manner in which this is accomplished that our material yields information.

Drinker and associates⁴⁰ have reviewed the literature dealing with the problem of the manner of discharge of red blood cells through the endothelial membrane. They suggest that the endothelial membrane of the sinuses is a continuous one and that groups of erythrocytes expand by growth onto the membrane and due to slight differences in pressure inside and outside the vessel are carried through the membrane. Maximow⁴⁸ also held that the membrane is continuous about all of the vessels of the marrow but that over masses of erythrocytes it may temporarily open or rupture to expose the cells to the circulating blood. The plasma passing through the temporary opening loosens the cells and carries them into the circulation. After discharge of the cells the thin endothelial lining membrane closes and the wall of the vessel regains continuity. Key⁵¹ has suggested that the maturation of the erythrocytes is accompanied by a decrease in their cohesiveness and that, as a result, the red blood cells are more readily washed out of the stroma spaces through openings in the endothelial wall into the blood stream. Bunting⁵⁰ has suggested that growth pressure may be a factor in causing migration of the red blood cells, though he does not state definitely whether or not he believes the endothelial membrane to be continuous or perforated.

The endothelial membrane of the venous sinuses of our material, as was pointed out previously, is continuous and distinct. Numerous instances of granulocytes and normoblasts passing through the endothelial membrane were found in our material and it appears to us that constriction of both granulocytes and normoblasts at the membrane is significant. We have concluded that the cells pass through the membrane between the margins of the endothelial lining cells and we further have concluded that the intrastromal growth of large quantities of erythropoietic tissue forced the cells through the membrane into the sinuses. We feel that growth pressure is one of the factors, though undoubtedly not the only factor, which brings cells of the erythrocyte series from the intervaseular tissue into the blood vessels.

The subject of the origin of the blood cells forms such an extensive mass of publications that it cannot be reviewed here. However, Downey⁵² and Cunningham and associates⁵³ have reviewed the literature and the reader is referred to those publications for detailed information on the subject. It should be noted that the latter authors and Doan and co-workers³⁵ have advanced the theory that in the bone marrow of adult animals the erythrocyte series takes

origin from the endothelial lining cells of hematopoietic capillaries. Many authors hold that the endothelial lining cells do not possess the potentiality of differentiating into hematopoietic cells and our material supports that view. In our series of animals, the bone marrow was stimulated by copper and iron therapy to produce large quantities of heteroplastic erythropoietic tissue, including large numbers of pronormoblasts. The new tissue was located extravascularly and in none of our preparations did the endothelial lining cells of the sinuses show a change in form or exhibit tendencies toward differentiation of any type.

As was pointed out in the section on results of this study, a special effort was made to determine the source and origin of the pronormoblasts found in such large numbers in our preparations. We did find instances of the reticular cells of the intervaseular stroma transforming into hemocytoblasts. Instances of such transformation were not numerous enough to account for the numbers of pronormoblasts produced. However, we did find that after therapy mitosis of the hemocytoblasts was greatly increased. We have concluded that the greater number of pronormoblasts arose by multiplication of hemocytoblasts and pronormoblasts already present at the time therapy was begun or of hemocytoblasts produced by transformation of stromal reticular cells after copper and iron feeding. In none of our preparations were we able to discover cells comparable to the "primitive cell" described by Sabin and associates⁵⁴ as the progenitor of granulocytes. Myeloblasts of the type described by Downey,⁵⁵ or hemocytoblasts as described by Bloek,⁵⁶ were present in the smears and sections of the bone marrow of our recovering animals. We conclude that they formed the stem cells for granulocytopoiesis and of the pronormoblasts of our preparations.

SUMMARY AND CONCLUSIONS

1. The blood values and bone marrows of sixty anemic rats killed at hourly intervals during the initial 48-hour recovery period after copper and iron treatment were observed in this investigation.

2. Hemoglobin and erythrocytes showed an increase in value beginning at 26 hours after treatment, and a slight but constant increase was continued from that hour to the end of the 48-hour observation period.

3. Normoblasts, eosinophiles, and heterophiles increased in value beginning at 12 hours after treatment, and a period of high and moderately high values extended from that hour to 26 or 28 hours after therapy, this being the period of first discharge of those cells from the bone marrow and the irregularity of values being due to variation in time and extent of response to therapy. Following that period of increase, the values for the various leucocytes continued higher than normal to the end of the period of observation.

4. The first histologic response of the bone marrow to copper and iron treatment was the development of heteroplastic erythropoietic tissue, including numerous pronormoblasts, and the highest degree of development of the tissue was found in the marrows of animals killed 18 to 26 hours after therapy. This period we have called the "critical period" of hematopoiesis of recovery.

5. The period of first great increase in numbers of normoblasts, eosinophiles and heterophiles coincided with critical period of hematopoiesis of the bone marrow and our histologic preparations showed a discharge of those cells into the blood stream by the bone marrow to occur during that period.

6. Erythropoiesis after the critical period was characterized by the disappearance of the heteroplastic process and the development of the homoplastic process, which was continued in increased volume to the end of our period of observation.

7. Erythropoiesis, including the heteroplastic erythropoiesis, and leucopoiesis developed extravasalarly in the intervacular stroma; our observations, therefore, support the view that all leucopoiesis and erythropoiesis in the marrow of mammals is extravascular.

8. The lining membrane of the sinuses of our preparations of the marrows was continuous and distinct and there was no rupture or destruction of the membrane during discharge of cells from the intersinusoidal tissues into the sinuses.

9. The development of large quantities of new hematopoietic tissue in the intervacular stroma, and the coincident discharge of cells into the sinuses, suggests that one of the factors concerned in the discharge of cells by the marrow is that of growth pressure within the intervacular stroma.

10. Origin of the pronormoblasts of the new erythropoietic tissue in our preparations was not, as suggested by some authors, from the vascular endothelium but from stromal reticular cells and by multiplication of hemoctoblasts and pronormoblasts. "Primitive cell" progenitors of granulocytes, as described by Sabin and associates, was not recognized in our preparations, and we have concluded that the hemoctoblasts, or myeloblasts, quite numerous in our preparations, were the progenitors of the granulocytes.

The author wishes to express his appreciation to Dr. Hal Downey and Dr. W. Bloom for their interest and suggestions.

LYMPHOCTOGENESIS IN HUMAN LYMPH NODES

R. DOROTHY SUNDBERG, PH.D.

MINNEAPOLIS, MINN.

e

THE origin, the development, and the widely varied morphologic changes, which are manifest during lymphocytemorphosis, have been and still are some of the most fundamental problems in all hematology. Classifications of the various types of cells grouped under the term lymphocyte are notoriously unsatisfactory, because lymphocytes lack the easily demonstrable specific characteristics such as the specific granules of granulocytes or the hemoglobin of developing erythrocytes. Although this lack of convincingly identifiable cytologic landmarks must be accepted as inevitable, the recent experiments showing that lymphocytes contain a protein identical with normal serum gamma globulin^{1, 2} and that antibodies are present in the lymphocytes of immunized animals^{3, 4} are dramatic examples of the importance of lymphocytes, examples which illustrate the need for renewed efforts at a clearer understanding of lymphocytemorphosis.

The origin of the lymphocyte in lymphatic tissue of laboratory animals and a comparison of the various types of lymphocytes to the myeloblasts of the bone marrow have been the subjects of research on the part of Downey and co-workers.⁵⁻¹² From these investigations and from studies of both blood and lymph nodes in infectious mononucleosis^{13, 14} and in subacute lymphatic leukemia,¹⁵ it was inferred that lymphocytemorphosis in nonleukemic human nodes probably closely simulated that which occurs in normal lymph nodes of rabbits and guinea pigs. The voluminous literature pertaining to the problems involved is partially reviewed in most of the publications but is most complete in the latest articles.^{11, 12}

The present report is a summary of a study of lymphocytemorphosis in human lymph nodes. The various cell types involved were compared with the myeloblast of human bone marrow, with the immature and mature lymphocytes of the lymph nodes of rabbits and guinea pigs, and with the types of lymphoid cells seen in the lymph nodes, blood, and bone marrow of cases of infectious mononucleosis, chronic lymphatic leukemia, and acute and subacute lymphatic leukemias.

MATERIALS AND METHODS

The 55 human lymph nodes studied were surgical specimens from which imprint preparations were made within a few minutes after their removal. They included 43 which showed no evidence of lymphoblastoma, 2 from chronic lymphatic leukemia, 9 from infectious mononucleosis (including the 8 nodes studied by Downey and Stasney¹⁴), and 1 from subacute lymphatic leukemia (that described by Stasney and Downey¹⁵). Eleven lymph nodes from rabbits and guinea pigs were useful in comparative studies; they have been described elsewhere.¹²

The 43 nonleukemic nodes included nodes from the lesser curvature of the stomach (4), the inguinal region (10), the axilla (24), and other locations (5). In all but four of the cases

From the Department of Anatomy, University of Minnesota.

in which the nodes showed no evidence of leukemin, the patients' clinical and hematologic findings were investigated and found to be within the range of those expected with the varied causes of hospitalization. In no case was there any evidence of leukemia.

Direct smears of bone marrow and smears made of the myeloid-erythroid layer obtained from heparinized centrifuged bone marrow¹⁶ from a wide variety of conditions other than leukemia were also examined in order that the various morphologic variations of the myeloblast might be correlated with the variations in the least differentiated types of lymphocytes visible in the nodes.

During the course of this investigation, blood and bone marrow received for diagnosis was also considered critically with reference to the various types of immature lymphoid cells encountered. The pathologic material reviewed which helped clarify the present problem included: (1) 50 cases of chronic lymphatic leukemia: blood, 34; blood and bone marrow, 16. (2) 31 cases of subacute or acute lymphatic leukemia: blood, 21; blood and bone marrow, 10. (3) 34 cases of infectious mononucleosis: blood, 33; blood and bone marrow, 1. (4) 12 cases of brucellosis: blood, 3; blood and bone marrow, 9.¹⁷

In order to determine the possible influence of blood on the cells from lymph nodes, a small amount of material from the mesenteric lymph node of a rabbit was scraped from a cut surface of the node and mixed with a small amount of blood. Smears were made from this mixture.

Lymph node imprints and smears of blood and bone marrow were stained with either the May-Grünwald-Giemsa combination or with Wright's stain. Lymph nodes were fixed in Helly's fluid, cut at 5 micra, and stained with hematoxylin and eosin or with Dominici's stain.

OBSERVATIONS

Lymph Node Sections.—Photomicrographs of sections of the lymph nodes have not been included because the development of lymphocytes from reticular cells has already been exhaustively studied by earlier investigators. The following works are singled out because they best illustrate the problem in question here. Downey and Weidenreich⁵ described and included beautiful illustrations (their Figs. 2 and 3) of the transformation of fixed reticular cells to lymphocytes in sections of guinea pig lymph nodes. Thiel and Downey¹⁸ described and illustrated the transformation of mesenchymal cells to hemocytoblasts and lymphocytes in the spleen of the pig embryo. Maximow¹⁹ gave excellent illustrations of the types of cells seen in germ centers of rabbit (his Figs. 7 and 8) and human (his Figs. 9 and 10) lymph nodes and in a germ center of human tonsil (his Fig. 11). Maximow also showed the formation of large lymphocytes from the embryonic reticular connective tissue in a newly formed lymph nodule in the mesentery of a rabbit (his Fig. 12). Klemperer²⁰ described and illustrated the transition from fixed reticular cells to hemocytoblasts in human pathologic lymph nodes and spleen.

Histopathology of Nonleukemic Nodes.—Since the development of lymphocytes rather than the types of pathologic changes occurring in lymph nodes is the subject of this report, the histopathologic changes observed in the lymph nodes can be considered only very briefly. None of the nodes examined was completely normal. Two nodes showed changes which might have resulted from mild physiologic (?) inflammation or age. Imprints from these nodes showed no evidence of active regeneration of lymphocytes. Five nodes which showed evidence of acute lymphadenitis were more normal in structure than any of the other specimens. Two of these nodes contained a fairly large number of small

germinal centers, and imprints showed an increase in the number of developing lymphocytes. Thirty-four nodes showed evidence of simple hyperplasia accompanied by chronic inflammatory changes. Of these thirty-four nodes, twenty-six were draining carcinomata, but only four of the latter showed the presence of tumor cells. The thirty-four simple hyperplastic nodes were those best adapted to this problem in that they all, regardless of the precipitating cause of hyperplasia, contained germinal centers in various stages of activity and showed increased numbers of developing lymphocytes in imprint preparations. Particularly interesting was the fact that the nodes draining the carcinomatous lesions showed pronounced lymphoid hyperplasia and many very large germinal centers, some of which were comparable in size to those seen in follicular lymphoblastoma. Only a very small number of macrophages containing the tingible Körper of Flemming²¹ were seen in the large number of these centers which were studied. The centers were not reaction centers in the proper sense; they were actively engaged in the production of lymphocytes, for they were filled with reticular cells and transitional stages between reticular cells and lymphocytes, and mitoses were numerous. Because some of the imprints from these nodes contained large aggregates of lymphoid cells including primarily reticular cells, reticular lymphocytes, and cells in various stages of mitosis, it was concluded that actual *germinal centers had been imprinted*, and the comparison of the immature cells in sections and in imprints could be made with considerable assurance.

Nine nodes, biopsy specimens from cases of infectious mononucleosis, showed the histopathologic alterations ascribed to this disease,¹⁴ and the imprints and smears showed a great increase in both the numbers of hematopoietic reticular cells and reticular lymphocytes²² and of leukocytoid lymphocytes of various types.¹³

Transformation of Reticular Cells to Lymphocytes.—It is recognized that undifferentiated, primitive, fixed, or syncytial reticular cells are capable of transforming either to phagocytic cells or to hematopoietic cells. In sections of the lymph nodes, reticular cells, even while still in syncytial arrangement, could be seen to have undergone partial differentiation. The differentiation to phagocytic cells could be recognized by the presence of slight coarsening of the nuclear chromatin and increased vacuolization of the cytoplasm as well as by the presence of ingested particles. The differentiation to lymphocytes was manifested both by coarsening of nuclear chromatin and by increased basophilia of the cytoplasm. Although these changes could be seen in fixed or syncytially arranged reticular cells, more often the differentiating reticular cells were free. In imprint preparations, undifferentiated reticular cells which were apparently free could also be found (Fig. 1).

The transformation of undifferentiated reticular cells to lymphocytes as it occurs in human lymph nodes was found to be essentially similar to that previously described for the nodes of rabbits and guinea pigs.¹² The transformation was a gradual process involving many morphologic cell types which differed but slightly from one another. The stages in the transformation appeared to include (1) undifferentiated reticular cells. (2) hematopoietic reticular cells,

(3) reticular lymphocytes, and (4) lymphocytes identical with those of the blood. Mitoses were found to be most numerous in cells which, because of their size and the character of their cytoplasm (Fig. 11), are believed to be hematopoietic reticular cells and reticular lymphocytes rather than the common large lymphocytes of the blood. No cells morphologically identical with the myeloblast (Figs. 14, 14', 15) of the bone marrow or with the lymphoblast (Figs. 16, 16', 17) of acute and subacute lymphatic leukemias were found to participate in the regeneration of lymphocytes in the nonleukemic nodes.

The undifferentiated reticular cell (Fig. 1) is a large cell which possesses a relatively large amount of cytoplasm. Its nucleus, like those of the lymphoid cells derived from it, is generally round or oval in shape. The nuclear chromatin is fine in character, stains a light reddish violet, and is distinctly demarcated from the pale pink-staining and relatively abundant parachromatin (karyoplasm). The chromatin pattern is delicate. In areas, it appears to be net- or sievelike; however, generally small clumps, chains, and strands of chromatin are also present, and the resulting nuclear pattern is not uniform as is that of most myeloblasts. Nucleoli may or may not be present. They are variable in size but are usually small blue-staining bodies which are partially obscured by overlying chromatin. The nuclear membrane is fine but distinct.

The cytoplasm of imprinted undifferentiated reticular cells is frequently damaged (Fig. 1); its actual boundaries are often not clearly visible. It appears to be watery, consisting of an abundant hyaloplasm with only a small amount of faintly basophilic spongioplasm. Vacuoles may be present; azure granules also can sometimes be found.

Figs. 2 and 2' show a cell very similar to the undifferentiated reticular cell. It has distinct cytoplasmic boundaries. Cells, not illustrated here, which occurred in the fields surrounding this cell contained phagocytosed material. Although the reticular cell in these figures might be considered an undifferentiated cell, in all probability it is a potential phagocyte (histiocyte). It is included in order best to illustrate the type of aggregation of chromatin which can be seen in the nuclei of reticular cells. (Compare the nuclear pattern of this cell with that of the hematopoietic reticular cell in Figs. 7 and 7'.)

In the transformation of the undifferentiated reticular cell to a one capable of forming blood cells, the most conspicuous change is a decrease in the amount of cytoplasm. The cytoplasm of hematopoietic reticular cells may be sparse (Figs. 3 and 4) but usually it is abundant (Figs. 5, 6, 7, 7'). Although basophilia of the cytoplasm is variable, most of the hematopoietic reticular cells have a grey-blue cytoplasm which is generally mottled or flaky in appearance and which often contains vacuoles (Figs. 3, 4, 5, 6, 7, 7'). The nuclear pattern may be almost identical with that of the undifferentiated reticular cell. (Compare nuclei of cells in Figs. 1 and 3.) The various cells classified as hematopoietic reticular cells because they resemble undifferentiated reticular cells and do not show indisputable evidence of transforming to lymphocytes are shown in Figs. 3, 4, 5, 6, 7, and 7'.

The next classifiable stage of differentiation is the reticular lymphocyte (Figs. 8 to 10). This cell has morphologic characteristics similar to those of

reticular cells and of lymphocytes. The recognition of this cell type as one distinct from the lymphoblasts of acute leukemia is of prime importance because small percentages of reticular lymphocytes may occur in the peripheral blood (Figs. 12, 12', 13) in benign lymphatic reactions.

Figs 1-7.—Cell types occurring in imprints of human nonleukemic lymph nodes which showed variable degrees of hyperplasia. All photomicrographs taken at same magnification ($\times 1440$).

Fig. 18.—Lymphocyte ($\times 1440$). Imprint of hyperplastic human lymph node.

Fig. 19.—Imprint of lymph node from chronic lymphatic leukemia. Hematopoietic reticular cells, reticular lymphocytes, lymphocytes, and mitosis ($\times 1440$).

Narrow-bodied cells similar to the cell at the right in Fig. 8 were most similar to the myeloblasts of the marrow and to the lymphoblasts of acute and subacute lymphatic leukemias. These narrow-bodied immature lymphoid cells differ from lymphoblasts in that considerable aggregation of chromatin is present. However, cells of this type may be encountered in the peripheral blood in acute and subacute lymphatic leukemias. It is assumed that these cells represent immature lymphocytes, but their phase of maturity is such that it is not possible to determine whether they have been derived from reticular cells or from lymphoblasts.

The stages occurring during the transition of reticular lymphocytes to cells which exhibit the characteristic morphology of the normal lymphocytes of the blood are numerous. The changes include a diminution in the cell size and in the size of both nucleus and cytoplasm. The nuclear chromatin becomes coarse and is arranged in heavy clumps of variable size. The latter stain deeply and tend to blend with the relatively sparse parachromatin. The nuclear membrane is coarse and distinct; nucleoli are not visible. The cytoplasm is colorless or pale blue and more hyaline in appearance. (Note lymphocytes in Figs. 18 and 3.)

Comparison to Myeloblasts.—As has been stated, no isomorphs of the myeloblasts of human bone marrow were found in the imprints of human non-leukemic lymph nodes. There is, as is commonly recognized, a marked similarity

Fig. 2'.—Histiocytic reticular cell, same as Fig. 2.

Fig. 7'.—Hematopoietic reticular cell, same as Fig. 7.

Fig. 12'.—Reticular lymphocyte, same as Fig. 12.

Fig. 14'.—Myeloblast, same as Fig. 14.

Fig. 16'.—Lymphoblast, same as Fig. 16.

(Drawn from original cells with the aid of photomicrographs. Magnification, $\times 1440$.)

between blast forms of all types, and the morphologic characteristics which distinguish the hematopoietic reticular cell from the myeloblast are neither numerous nor prominent. Since both myeloblasts and lymphoblasts may be derived from reticular cells, morphologic evidence of the reticular derivation of either of these cells is sometimes present. The uniformity of nuclear structure in both myeloblasts and lymphoblasts might well be the result of repeated mitoses without subsequent differentiation.

Table I is included in order to facilitate comparison of the morphologic characteristics most commonly encountered in hematopoietic reticular cells, reticular lymphocytes, large lymphocytes, and myeloblasts or lymphoblasts. These characteristics are, of course, simply average findings.

TABLE I. COMPARISON OF IMMATURE LYMPHOCYTES WITH LARGE LYMPHOCYTE AND MYELOBLAST

Cell type	Hematopoietic reticular cell	Reticular lymphocyte	Large lymphocyte	Myeloblast or lymphoblast
Cell size	23 by 19 micra	20 by 17 micra	14 by 12 micra	16 by 15 micra
Nuclear size	17 by 14 micra	16 by 13 micra	11 by 9 micra	14 by 13 micra
Nuclear shape	Round or oval	Round or oval	Round or oval	May be irregular
Nuclear pattern	Irregular	Irregular	Irregular	Uniform
Chromatin				
Staining	Light reddish violet	Reddish violet	Purple	Light reddish violet
Nature	Small particles of variable size; chains; strands of granules	Similar to hematopoietic reticular cell but larger masses; more strands of granules	Large angular masses; only very few chains	Fine, sieve- or netlike; sometimes granular or stippled
Parachromatin				
Amount and nature	Abundant and very distinct	Abundant and distinct	Sparse and indistinct	Not overly abundant but distinct
Staining	Pale pink	Pale pink to pale reddish violet	Pale reddish violet to gray blue	Pale pink
Nucleoli				
Number	Variable	Variable	Not visible	Variable
Diameter	1 to 7 micra	1 to 7 micra		1 to 3 micra
Staining	Pale blue	Pale blue to blue		Pale blue
Shape	Rounded or irregular	Rounded or irregular		Round or oval
Character	Indistinct	Indistinct		Distinct
Nuclear membrane	Fine, distinct	Coarse, less distinct	Coarser, less distinct	Very fine, indistinct
Cytoplasm				
Staining	Gray blue to colorless	Deep blue to colorless	Pale blue to colorless	Pale blue
Character	Mottled and flaky	Mottled and flaky	Usually homogeneous	Usually homogeneous
Vacuoles	Common	Common	Uncommon	Uncommon
Azure granules	Rare	Rare	Uncommon	Common in myeloblast; uncommon in lymphoblast

Lymphocytogenesis in Animal Lymph Nodes.—Lymphocytogenesis in human lymph nodes was found to be remarkably similar to lymphocytogenesis in the nodes of rabbits and guinea pigs. In the hyperplastic but nonleukemic human nodes, hematopoietic reticular cells were, however, more numerous than

in the nodes of rabbits and guinea pigs. In the nodes of rabbits and guinea pigs, reticular lymphocytes, most of which possessed a more deeply basophilic cytoplasm than did the reticular lymphocytes of human nodes, were far more numerous than hematopoietic reticular cells, and mitoses were most numerous in these reticular lymphocytes. No important morphologic changes were produced by mixing the cells from a rabbit's lymph node with blood.

Lymphocytoogenesis in Infectious Mononucleosis.—Lymphocytoogenesis in infectious mononucleosis resembled that seen in both the simple hyperplastic human nodes and the animal nodes. As would be expected, however, there was more evidence of active regeneration of lymphocytes in the nodes from infectious mononucleosis than in any of the other nonleukemic nodes. The following features were recognized: (1) Hematopoietic reticular cells and reticular lymphocytes were more numerous in many of the lymph nodes from infectious mononucleosis than in most of the other nonleukemic nodes, and reticular lymphocytes were far more numerous than hematopoietic reticular cells. (2) The cytoplasm of the immature cells seen in infectious mononucleosis generally showed pronounced basophilia, and in many of these cells the cytoplasm was almost completely homogeneous. (3) Some of the extremely basophilic reticular lymphocytes appeared to function as precursors of plasma cells. However, transitions between these basophilic reticular lymphocytes (plasmablasts of Moeschlin^{23, 24}) and the Type I leukocytoid lymphocyte of Downey and McKinlay²⁵ were also prominent. (4) Mitoses were more numerous in many of the lymph nodes from infectious mononucleosis than in any of the other nonleukemic nodes. Many more mitoses appeared to occur in the reticular lymphocytes of the lymph nodes of infectious mononucleosis than in the reticular lymphocytes of the other nonleukemic nodes. (5) In the lymph nodes from infectious mononucleosis, transitions between the reticular lymphocytes and the leukocytoid lymphocytes of infectious mononucleosis were numerous, whereas such transitions were very rare in the other nonleukemic nodes.

The bone marrow from one case of infectious mononucleosis showed a relative (29.5 per cent) and absolute lymphocytosis (myeloid-erythroid volume, 18.5 per cent). Hematopoietic reticular cells, reticular lymphocytes, and leukocytoid lymphocytes were numerous. All three of these cell types were morphologically distinct from the myeloblasts of this marrow.

Lymphocytoogenesis in Chronic Lymphatic Leukemia.—Lymph nodes from two cases which exhibited the typical clinical and hematologic findings of chronic lymphatic leukemia were studied. The node from the first case had been palpable for a long period of time; the node from the second case had become noticeable in a period of about three weeks. The former node was considered to be relatively static, and it will be designated Node S; the latter was one which had undergone rapid growth, and it will be designated Node G. Each of these nodes showed in section preparations the characteristic features of chronic lymphatic leukemia. In Node G, however, reticular hyperplasia and mitoses were more prominent.

The imprint material from Nodes S and G showed such a striking lack of similarity that the relatively similar appearing sections from these two nodes seemed almost incomprehensible.

Node S showed an almost completely monotonous picture of large lymphocytes. These lymphocytes had a nuclear pattern only slightly different from that of the large lymphocytes of normal blood. The chromatin masses were neither as heavy nor as deeply stained as those of ordinary lymphocytes, and the parachromatin was more clearly visible than is that of normal lymphocytes. The cytoplasm was less abundant than that of most lymphocytes, but it was not as sparse as that of the lymphoblasts of acute lymphatic leukemia or as that of many of the myeloblasts of human nonleukemic bone marrow. The most prominent feature was not, however, this slightly abnormal appearance of the lymphocytes, for lymphocytes of this type can be found in almost any lymph node imprint. The striking feature was the lack of variation in cell type. Cells which appeared less differentiated than these large lymphocytes were present, but they were neither particularly numerous nor conspicuous. Some resembled the hematopoietic reticular cells and reticular lymphocytes of nonleukemic nodes, but most of them showed an even more striking clarity of nuclear detail than that seen in similar cells from nonleukemic nodes. Nucleoli, particularly, seemed more distinct. Yet, none of the cells seen was identical with the myeloblast (Figs. 14, 14' 15) of the bone marrow or with the lymphoblast (Figs. 16, 16', 17) of acute lymphatic leukemia. All of the immature cells showed morphologic patterns interpreted as being indicative of their close relationship to reticular cells.

Node G, in contrast, showed a picture which was completely lacking in the monotonous uniformity of cell type which was seen in Node S. Although all sizes of lymphocytes were present, the lymphocytic picture was overshadowed by tremendous numbers of cells many of which were almost identical to the hematopoietic reticular cells and reticular lymphocytes that occurred in the nonleukemic nodes. (Note, for example, the striking similarity of the largest cell shown in Fig. 19 to the hematopoietic reticular cell shown in Figs. 7 and 7'. Compare also the large cells in Figs. 5 and 19; both have large and irregularly shaped, indistinct nucleoli, and both have vacuoles in both nuclei and cytoplasm. Finally, compare the mitotic figure in Fig. 19 with that in Fig. 11.) Many cells which were morphologically identical with the hematopoietic reticular cell in Figs. 7 and 7' were present in Node G. Everywhere throughout all of the imprints of Node G hematopoietic reticular cells, along with intermediate stages between them and lymphocytes, and mitoses were numerous. In fact, one might compare the picture as a whole to one which could be produced by imprinting one mammoth germinal center. This degree of hyperplasia was not, however, encountered in any of the nonleukemic human or animal nodes. In imprints from Node G, as in those from Node S, there was a striking clarity of cytologic detail. Because it was suspected that this might be caused by some variation in technique, nonleukemic and leukemic nodes were stained simultaneously and in an identical manner. The resulting preparations showed that the method of staining was not the explanation for this phenomenon.

The degree of reticular hyperplasia which was evident in Node G is considered unusual for chronic lymphatic leukemia. Most of the nodes from chronic lymphatic leukemia which have been described and which are encountered in routine autopsy material show the monotonous uniformity of pattern seen in

Node S of this report. In the case from which Node G was removed, neither the patient's clinical condition nor his hematologic findings suggested an exacerbation of the leukemic process. The best explanation for the active regeneration of lymphocytes seen in the node seemed to be that the node had undergone recent rapid growth.

Lymphocytogenesis in Acute and Subacute Lymphatic Leukemias.—Lymphoblasts from acute lymphatic leukemias in which the peripheral blood smears showed large numbers of cells of this type are shown in Figs. 16, 16', and 17. These cells are very similar to the cells seen in the imprints of the biopsied lymph nodes studied by Stasney and Downey,¹⁵ and they are also similar to many of the cells seen in the peripheral blood of their case. Since no lymph nodes from acute or subacute lymphatic leukemia were obtained during the course of this study, conclusions were based upon a comparison of the cell types seen in nonleukemic nodes with the lymphoblasts seen in the peripheral blood and in the bone marrow of cases of acute and subacute lymphatic leukemia and with the lymphoblasts seen in the imprints of the nodes studied by Stasney and Downey.

The nonleukemic nodes did not contain cells morphologically identical with the leukemic lymphoblasts. The leukemic nodes and the peripheral blood smears and bone marrow smears from the various cases of acute and subacute lymphatic leukemias contained large numbers of lymphoblasts many of which could not be distinguished from myeloblasts. In addition, the smears from the acute and subacute leukemias also contained occasional hematopoietic reticular cells and reticular lymphocytes as well as immature lymphocytes with narrow cytoplasmic bodies similar to the cell at the right in Fig. 8. The latter type of cell can be found in relatively normal and in hyperplastic nodes, in the blood, nodes, and marrow of lymphatic leukemia, and also occasionally in the blood of normal children.

REVIEW OF LITERATURE AND DISCUSSION

Publications presenting detailed morphologic studies of lymphocytogenesis as seen in both imprint and section preparations of surgically biopsied, human nonleukemic nodes have not been encountered. However, various investigators who have aspirated material from lymph nodes for diagnostic purposes have discussed regeneration of lymphocytes in normal nodes.

Fleischhacker and Klima²⁵ stated that "In order to get a criterion about the morphology of normal lymph nodes, we punctured patients with good available but otherwise unchanged lymph nodes." They found that smears of these normal nodes showed predominantly ripe lymphocytes, but a few larger, less mature forms were present and were interpreted as lymphoblasts. They made a distinction between myeloblasts of myelogenous leukemia and lymphoblasts, but they made no distinction between the lymphoblasts of normal nodes and those of lymphatic leukemia.

Tischendorf²⁶ confirmed some of the conclusions of the present study by stating that the puncture of healthy nodes was hardly possible and by adding that when lymph nodes are large enough to be punctured, they are probably pathologic. Tischendorf, however, also described typical lymphoblasts in nodes

and claimed they were increased in number in hyperplasias and in leukemias. He clarified his interpretation of the term lymphoblast by stating that in some leukemias, large cells with spongy nuclei containing intensively blue and distinct nucleoli, and whose protoplasm was delicate and often "fringed out," could be seen. These cells *may*, according to him, be stem cells which may be derived from the capillary endothelium. Of particular interest was the fact that Tisehendorf also discussed a case of chronic lymphatic leukemia from which the lymph node material showed large numbers of immature cells (his stem cells and lymphoblasts). In lymph aspirated from the nodes of infectious mononucleosis, he found cells two times the size of lymphocytes with fine nuclei which "lie in a deep dark blue cytoplasm." These cells were regarded as characteristic cells of infectious mononucleosis which showed no resemblance to the immature lymphoid cells of relatively normal nodes. Tisehendorf, like Fleischhacker and Klima,²⁵ considered myeloblasts and lymphoblasts as morphologically distinct cell types.

It is difficult to determine how much agreement there is between the present findings and those of the German authors.^{25, 26} In the present study, the term lymphoblast is reserved, as it has been in the preliminary studies of lymphocytopoiesis, for the immature lymphoid cell of acute and subacute lymphatic leukemias. The lymphoblast is considered to be a cell which is frequently morphologically indistinguishable from the myeloblast. Fleischhacker and Klima²⁵ and Tisehendorf²⁶ claimed separate identity for myeloblasts and lymphoblasts, but they found lymphoblasts in normal as well as in leukemic nodes. Although Tisehendorf claimed that the immature cells of infectious mononucleosis bore no resemblance to the immature cells of relatively normal nodes, it seems extremely likely that the cells which he observed in infectious mononucleosis would correspond to the hematopoietic reticular cells and reticular lymphocytes of the present report. As has been previously discussed, the immature lymphoid cells of infectious mononucleosis are, except for more intense cytoplasmic basophilia, almost identical to those seen in other hyperplastic nodes.

Moeschlin,²⁴ in his report on a study of three cases of infectious mononucleosis in which he studied aspiration material from lymph nodes, bone marrow, and spleen as well as the blood, showed that much of his work confirmed the previous work of Downey and Stasney.¹⁴ However, in this paper and in a previous work on lymph node aspiration material from rubeola,²³ Moeschlin described two immature cells which he felt were specific cell types. The first of these cells was the plasmablast, and since he could see transitions between this cell and plasma cells, he felt that it was much more likely that the plasma cells formed in lymphatic tissue were derived from this plasmablast than from lymphocytes. As nearly as can be determined from his descriptions and his Fig. 4, *a*,²³ Moeschlin's plasmablast appears to correspond to some of the unusually basophilic hematopoietic reticular cells and reticular lymphocytes seen in the present investigation.

In view of Moeschlin's hypothesis, however, nodes of all types were studied in an effort to determine whether the large reticular elements should be considered as plasmablasts. Transitions between reticular lymphocytes and plasma cells were encountered, but transitions between lymphocytes and plasma cells

were also often seen in nodes where no cells resembling the plasmablasts of Moeschlin could be found, and cells corresponding well with his plasmablast were found in nodes which contained few or no plasma cells. Therefore, in spite of Moeschlin's excellent figures, it does not seem correct that he designate the extremely immature hematopoietic reticular cell as a specific plasmablast and ignore the fact that this cell may function as a parent cell for all the lymphatic elements of the nodes, including plasma cells. (Note plasma cell in Fig. 3.)

The second immature cell type was Moeschlin's²⁴ lymphatic monoblast. This cell (his Fig. 5, 1), which occurred in increased numbers in infectious mononucleosis appears to correspond to the reticular lymphocytes of the present investigation. Moeschlin called it a lymphatic monoblast because transitional stages occurred between it and a lymphatic cell (which showed an indented nucleus and coarser chromatin), the lymphatic monocyte. The latter cell corresponds to Downey and McKinlay's¹³ leukocytoid lymphocyte, Type I. Here, again, terminology is confusing. Moeschlin's term lymphatic monoblast is an acceptable descriptive term, for certainly some of the leukocytoid lymphocytes of infectious mononucleosis resemble monocytes and might be called lymphatic monocytes. However, cells entirely similar to Moeschlin's lymphatic monoblasts (reticular lymphocytes of the present investigation) were numerous in nodes which were hyperplastic but which showed almost no lymphocytes with indented nuclei resembling the lymphatic monocytes of Moeschlin.

Although Moeschlin agreed with Downey and Stasney¹⁴ that the majority of young cells in the nodes of infectious mononucleosis should not be called lymphoblasts, he found lymphoblasts in normal and in other nonleukemic nodes. It is difficult to determine just what type of cell his lymphoblast (Fig. 7, d²³) actually is. His figure showed a cell approximately 17 micra in diameter with a narrow rim of cytoplasm and prominent nucleoli, but with relatively coarse chromatin. Although no cells identical with Moeschlin's lymphoblast were seen in the nonleukemic nodes studied, cells of about the same size, with relatively coarse chromatin and with nucleoli, were occasionally seen in the poorly preserved parts of the imprints. In these same areas, it was often possible to see nucleoli in lymphocytes of all sizes. Because the morphologic picture seemed to be one due to damage and distortion, cells of this type were not included in the present study.

Although literature dealing with lymphocyto-genesis in human nonleukemic nodes is sparse, there is a voluminous literature (the product largely of studies of animal or leukemia material) in which numerous authors express their views of the fundamentals of hematopoiesis. Downey discussed the early literature in 1927⁶ and in 1938.¹¹ In a more recent publication,¹² it was again assumed that lymphocyto-genesis in human nonleukemic nodes might closely parallel that seen in the nodes of rabbits and guinea pigs, and the discussion included in that report considered the various theories proposed for regeneration of lymphocytes. Since the results of the present investigation support the conclusions drawn in that study, no similar discussion will be included here.

A few points, however, require further clarification. The introduction of new terms into a science already encumbered by terminology is not desirable. All precursors of lymphocytes obviously are lymphoblastic in function, but im-

fortunately the term lymphoblast has been used in the past and is used in present-day clinical hematology to identify the most prominent lymphoid cell found in the blood in acute and subacute lymphatic leukemias. Most hematologists recognize the marked similarity of lymphoblasts and myeloblasts. Since cells conforming in morphology to the common conception of the term lymphoblast were not found in the nonleukemic nodes, it seems unwise to employ the name lymphoblast in *any* discussion of normal lymphocytopoiesis. In an earlier publication,¹² lymphocyte regeneration was reconstructed as proceeding from undifferentiated reticular cells to reticular lymphocytes either directly or through a blast stage called the hematopoietic reticular cell or hemohistioblast. Mitoses were found to be most numerous in cells which appeared to be either hematopoietic reticular cells or reticular lymphocytes. Numerous transitional stages occurred between these two cell types, and the transition to ordinary lymphocytes was also a gradual one.

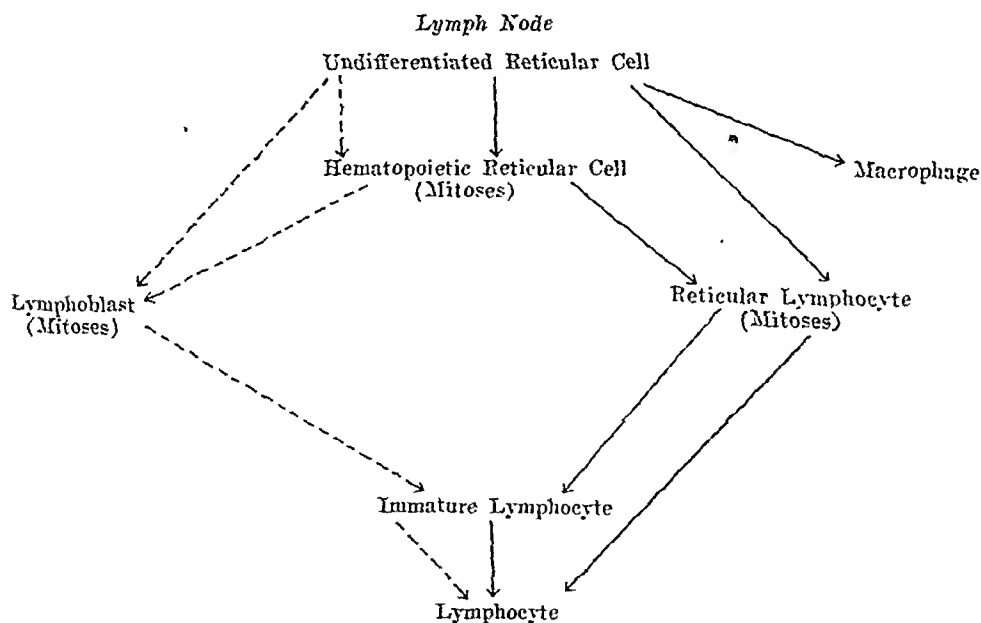

The problem is, for the most part, one of academic importance. However, in many instances an understanding of lymphocytopoiesis is extremely valuable from a diagnostic standpoint. Various conditions are associated not only with peripheral lymphocytosis but also with the presence of a small percentage of immature lymphoid cells in the peripheral blood. These conditions are considered lymphatic reactions, reactions in which occasional normal immature lymphoid cells, reticular lymphocytes, enter the circulation. Reticular lymphocytes have been encountered in infectious mononucleosis, brucellosis, infectious hepatitis, some acquired hemolytic anemias, and in conditions in which there was pronounced eosinophilia. Because reticular lymphocytes may contain nucleoli and may exhibit a fine nuclear pattern (Figs. 12, 12', 13), they are sometimes mistaken for lymphoblasts, and erroneous diagnoses of leukemia are made. When it is understood that these reticular lymphocytes are merely immature lymphoid cells which may occur in any hyperplastic lymph node and which, when in the peripheral circulation, are usually simply the result of a benign left shift in lymphocytopoiesis, many of the problems of diagnosis will be simplified.

One noteworthy exception exists. In most chronic lymphatic leukemias, immature lymphocytes were not numerous in the peripheral blood. When immature cells were present, they were more similar to the reticular lymphocytes of infectious mononucleosis and of human nonleukemic nodes than to the lymphoblasts of acute leukemias. In fact, as has been stressed elsewhere,²² there are cases of chronic lymphatic leukemia in which the peripheral blood so closely resembles that of some cases of infectious mononucleosis that a differential diagnosis on the basis of an examination of the blood smear is not always possible. The findings of reticular hyperplasia in node G is, therefore, not surprising; it serves merely to clarify previous impressions. Data available at the present time suggest that in chronic lymphatic leukemia, lymphocytopoiesis closely parallels that seen in nonleukemic nodes. The clarity of morphologic detail in both mature and immature cells is, however, striking in many cases. It is possible that this clarity is the result of frequent mitoses with the production of enormous numbers of almost identical cells.

The presence of lymphoblasts in acute and subacute lymphatic leukemia and their absence in nonleukemic nodes is difficult to explain. Since they were not found in the present investigation, it is assumed that they do not occur in significant numbers in nonleukemic nodes. Transitional stages between the reticular lymphocytes of nonleukemic nodes and normal lymphocytes are often morphologically identical with transitional stages between lymphoblasts and normal appearing lymphocytes. Only the immature cells differ. That reticular cells may differentiate to lymphoblasts which undergo numerous mitoses and little if any differentiation is one explanation of the phenomenon.¹⁵ It appears to be a very likely explanation, for in nodes, marrow, or blood from subacute and acute lymphatic leukemias, a few cells which show evidence of reticular origin can almost always be found.

Transitional stages encountered in this study can be organized into a diagrammatic type of working hypothesis (Table II).

TABLE II. LYMPHOCYTOGENESIS

——, Transitional stages encountered in simple hyperplastic nodes, in nodes from infectious mononucleosis, and in nodes from chronic lymphatic leukemia.

- - - - -, Transitional stages encountered in acute and subacute lymphatic leukemias.

SUMMARY

Relatively normal human lymph nodes, like the normal lymph nodes of rabbits and guinea pigs, do not contain cells morphologically identical with the myeloblasts of the bone marrow. The immature lymphoid cells (hematopoietic reticular cells and reticular lymphocytes) which are the progenitors of lymphocytes are morphologically distinguishable from myeloblasts. On this basis, it can be said that morphologic and functional dualism exists in normal adult

hematopoiesis; the hematopoietic reticular cell functions as a stem cell for lymphocytes, and the myeloblast functions as the stem cell for myeloid elements.

The results of the present investigation indicate that this condition prevails except in some cases of acute and subacute lymphatic leukemias where cells called lymphoblasts, many of which are morphologically indistinguishable from myeloblasts, occur in the blood, the lymph nodes, and the bone marrow.

THE CLINICAL SIGNIFICANCE OF CELLULAR GIGANTISM IN HUMAN ERYTHROPOIESIS

LAWRENCE BERMAN, M.D.
DETROIT, MICH.

PLURINUCLEAR erythroblasts and pluripolar mitoses among erythroblasts in megaloblastic erythropoiesis have been described by a number of authors.^{1, 7, 12-16, 19, 20} On the other hand, their occurrence in nonmegaloblastic erythropoiesis, which has been mentioned or illustrated by a few authors,^{13-15, 17, 18, 20} is considered to be very unusual.^{5, 8, 11, 15} In 1943 Limarzi and Levinson¹⁵ reported a case in which they found what was considered to be a hitherto undescribed type of erythropoiesis in human sternal marrow. This was characterized by the formation of giant erythroblasts, giant plurinuclear erythroblasts having two or more nuclei, giant erythroblasts with lobulated nuclei, and abnormal mitoses with three or more poles. The erythroblasts appeared to be neither megaloblastic nor normoblastic; they were so abnormal and large that they were called giantoblasts. The authors regarded the changes as irreversible and indicative of a cancerous process and proposed the terms erythroma or erythroblastoma. In 1944 Schleicher¹⁹ reported two cases with similar atypical erythroblasts, chiefly of orthochromic type. He regarded them as an expression of defunct reticulum, thereby implying that the changes were terminal or irreversible. Recently, Schwarz²⁰ reported a study of the question of cellular gigantism in human hematopoiesis based on observation of sternal marrow smears; he summarized the occurrence of giant plurinuclear erythroblasts and pluripolar mitoses among erythroblasts as phenomena independent of the type and condition of hematopoiesis. He concluded that gigantism does not depend on a morbid condition of erythropoiesis since it occurs in normal as well as in pathologic marrows. A somewhat contrary view regarding the significance of plurinuclear erythroblasts is expressed by Leitner¹³ who states that atypical cell divisions are present mostly in serious disorders and are found in large numbers only in severe hemopathies.

In this laboratory we have observed a fairly regular appearance of plurinuclear erythroblasts in both normal and pathologic marrows, exclusive of the megaloblastic marrows in which it is generally agreed that these changes are common. In view of the alleged rarity of these conditions in nonmegaloblastic marrows (Limarzi and Levinson¹⁵) in contrast to its commonly observed occurrence in our experience and that of others (Schwarz²⁰ and Leitner¹³), and the divergence of opinion regarding their proper interpretation, it is desirable that material be reviewed for the purposes of shedding light on the following: (1) the incidence of the phenomena under question in normal and pathologic marrows, (2) the question of the reversibility of the changes, (3) the question of

From the Departments of Pathology and Medicine, Wayne University College of Medicine, and the City of Detroit Receiving Hospital, and the Anemia Laboratory, Out-patient Department, Harper Hospital.

whether or not the changes are of agonal or terminal nature, (4) the question of whether or not erythropoiesis of the peculiar type here considered represents a new, different, or cancerous form of development, and (5) the presentation of data which may aid in the eventual interpretation of the clinical significance of such findings. For these objectives it is essential that cases for study are selected because of a significantly high incidence of plurinuclear erythroblasts, that more than a single marrow examination be available during life, and that none of the patients be in a terminal or agonal state. These criteria are fulfilled by the eight cases with pathologic marrows to be described in detail. In addition, control studies were carried out on eight normal individuals.

MATERIAL AND METHODS

The eight pathologic cases selected included one patient each with pernicious anemia, anemia associated with chronic blood loss, lymphoblastoma, monocytic leucemia, congenital hemolytic anemia before and after splenectomy, idiopathic thrombocytopenic purpura before and after splenectomy, cirrhosis of the liver, and acute hepatitis. The eight normal individuals selected for the control studies were healthy white males whose ages ranged from 18 to 53 years. They were chosen on the basis of their having had no serious illnesses and of having a sense of well-being, normal hematologic, chemical, and metabolic findings including the following: erythrocyte, leucocyte, platelet and reticulocyte counts, differential counts of leucocytes, bleeding and clotting times, capillary fragility, prothrombin and blood urea nitrogen levels, liver function tests, urinalyses, sedimentation rate, basal metabolic rate, electrocardiogram, stereoscopic chest x-ray, and thorough physical examination. In each case the sternal marrow was obtained, prepared, and examined by the methods previously described as routine for this laboratory.² Differential counts of the nucleated cells in the smears were based on examination of a minimum of 1,000 cells.

The age range of the control cases is not identical with that of the eight pathologic cases studied, but it is felt that they form a homogeneous age group with regard to sternal marrow findings, since Jacobsen's¹⁰ study of bone marrows in seventy normal individuals ranging in age from 15 to 93 years reveals no significant variation due to differences of age. Furthermore, the fact that all the normal individuals in the control series are males does not detract from its reliability, since Segerdahl's²¹ study of normal myelograms of 61 adult males and 49 adult females of comparable ages revealed only very slight variations in the myelograms due to difference of sex.

TERMINOLOGY

It has been pointed out that the phenomena of plurinuclearity and pluripolarity of mitosis are seen in both leucocytes and erythroblasts* of the sternal marrow.^{13, 20} The present study is confined to the interpretation of these changes affecting erythroblasts. In the papers already cited, various terms have been used to denote the abnormal erythroblasts. Limarzi and Levinson refer to a very large uninuclear precursor of the abnormal cells and the large plurinuclear erythroblasts as giant erythroblasts and giantoblasts after Ehrlich and Lazarus.⁶ Schleicher refers to the large plurinuclear orthochromic cells as giant orthochromic erythroblasts. Schwarz described binucleated and plurinucleated erythroblasts and pluripolar mitoses. His descriptions and illustrations clearly indicate the identity of these forms with the plurinuclear cells and pluripolar mitoses described by the other authors. In our material, all types of plurinuclear erythroblasts as well as those with lobulated nuclei described by the other authors are represented, although, as will be shown, examples of such cells at the proerythroblast or orthochromic levels are very rare in normal marrow.

*The term erythroblast as used herein denotes any nucleated red cell which may undergo maturation changes from proerythroblast through basophilic, polychromatophilic, and orthochromic stages before final denucleation.

MORPHOLOGY OF PLURINUCLEAR ERYTHROBLASTS AND PLURIPOLAR MITOSES AMONG ERYTHROBLASTS

Limarzi and Levinson described three main types of abnormal erythropoiesis. In the first type, a giant uninuclear erythroblast gave origin to plurinuclear cells by a series of multiple and complicated mitotic divisions without cytoplasmic division. The second type was characterized by a process of folding, indentation, lobulation, and constriction of the original nucleus so that eventually several

- 3.—Case 1. Trinuclear early basophilic erythroblast 26 x 36 microns.
- 4.—Case 2. Trinuclear proerythroblast 25 x 27 microns.
- 5.—Case 1. Trinuclear orthochromic erythroblast 18 x 27 microns.
- 6.—Case 1. Sesquicentric erythroblast 21 x 26 microns.
- 7.—Case 2. Late polychromatophilic erythroblast with many nuclear masses (karyorrhexis ?) 25 x 37 microns.
- 8.—Case 1. Late polychromatophilic erythroblast with fused or lobulated nuclei 20 x 30 microns.
- 9.—Case 1. Late polychromatophilic erythroblast with fused or lobulated nuclei 20 x 30 microns.

independent nuclei were produced in a single cell. The third type was characterized by complete or incomplete complicated amitosis without cytoplasmic division. In Schwarz's material, examples of all these forms are described and illustrated. The giant orthochromic erythroblasts in Schleicher's material had diameters ranging from 15.8 to 39.6 microns. The nuclei were either lobulated, fragmented, or consisted of from five to eight deeply staining masses of irregular size.

 13—Case 2 Incomplete cytokinesis in quadrinuclear early basophilic erythroblast 25 x 37 microns
 14—Case 2 Incomplete cytokinesis in two binuclear basophilic erythroblasts
 15—Case 1 Tripolar mitosis with aberrant chromosomal mass in basophilic erythroblast 23 x 27 microns
 16—Case 1 Quadripolar mitosis with aberrant chromosomal mass in polychromatophilic erythroblast 19 x 30 microns
 17—Case 1 Irregular pluripolar mitosis in polychromatophilic erythroblast 20 x 27 microns
 18—Case 1 Pluripolar mitosis with at least 7 asters in late polychromatophilic erythroblast 26 x 28 microns

The published detailed descriptions and illustrations of plurinuclear cells and pluripolar mitoses^{15, 17, 19, 20} in both megaloblastic and nonmegaloblastic marrows are very complete and require little elaboration. In Plates I and II²¹ are illustrated examples of such cells from one normal and three pathologic cases in our material. Examples from a case of pernicious anemia are omitted because of the general agreement as to their common occurrence in that disease. The identity of the cells illustrated and those represented by others is clear. It is of special interest that the condition of plurinuclearity in our material did not interfere with the relative progress of nuclear and cytoplasmic maturation. With very few exceptions, plurinuclear cells with basophilic erythroblastic nuclei were found to have cytoplasm characteristic of that maturation level. Similar normal relationships were observed in the polychromatophilic and orthochromic levels. These findings are in agreement with those of Schwarz whose study indicates that plurinuclearity does not interfere with the development and functional activities of the erythroblasts. Furthermore, the type of maturation and the morphologic forms of both nuclei and cytoplasm in the plurinuclear cells, in every instance, conformed to that of the prevailing type of erythropoiesis. In the normoblastic marrows (Cases 2, 4, 5, 6, 8, in addition to all normal cases) the plurinuclear cells had nuclear and cytoplasmic characteristics entirely similar to those of the remaining uninuclear normoblasts; in the megaloblastic marrow (Case 3), not only did the nuclear and cytoplasmic characteristics of the plurinuclear cells conform to that of the megaloblasts which predominated, but the relative rates of maturation of nuclei and hemoglobinization of cytoplasm were characteristic of the cells of the megaloblastic line, as described elsewhere.³ In two instances (Cases 1 and 7) erythropoiesis involving the uninuclear erythroblasts could not be identified as either normoblastic or megaloblastic. The erythroblasts were classified as dysplastic, being somewhat intermediate in morphology between normoblasts and megaloblasts. In these marrows the plurinuclear erythroblasts and the remaining uninuclear erythroblasts had similar morphologic features. The sizes of the giants were approximate multiples of those of the corresponding stages of the uninuclear cells, roughly directly proportional to the amount of nuclear material, that is, the number of nuclei in each cell.

INCIDENCE OF PLURINUCLEAR ERYTHROBLASTS IN NORMAL HUMAN STERNAL MARROW

The literature does not contain statistical data concerning the incidence of plurinuclear erythroblasts or pluripolar mitoses among erythroblasts in normal human sternal marrow. Limarzi and Levinson stated that the occurrence of normal bipolar and pathologic multipolar mitosis of erythroid cells in the same marrow is an unusual finding in the adult. Schwarz stated that gigantism occurs in normal as well as in pathologic marrows, and also that he repeatedly encountered pluripolar mitoses in normoblastic regeneration, even in normal marrows. The myeloid:erythroid ratios and incidences of plurinuclear erythroblasts in normal individuals are shown in Table I.

*The photomicrographs were prepared by Frank N. D. ...

TABLE I. MYELOID:ERYTHROID RATIOS AND INCIDENCE OF PLURINUCLEAR ERYTHROBLASTS IN STERNAL MARROW OF NORMAL INDIVIDUALS

CASE	AGE	M:E RATIO	PNE(0/100)	TOTAL ERB
1	18	3:1	5.0	13,065
2	22	2:1	2.0	5,010
3	24	2:1	2.2	5,011
4	30	2:1	1.2	5,006
5	31	2:1	1.0	5,005
6	36	2:1	2.8	5,014
7	45	2:1	1.0	5,005
8	53	2:1	5.1	10,051

M:E ratio, Myeloid: erythroid ratio.

PNE (‰), number of plurinuclear erythroblasts per 1,000 uninuclear erythroblasts.

Total ERB, number of erythroblasts examined.

*The myeloid: erythroid ratio represents the ratio of the number of leucocytes of myeloid origin, including monocytes, to the number of erythroblasts in the smears. It must be pointed out that the value is relative, not absolute. A decreased M:E ratio is indicative of a relative increase of erythropoiesis or relative decrease of myeloid leucopoiesis. The ratio cannot be used to determine absolute increase or decrease of erythropoiesis. However, our practice includes the preparation of gross marrow units which are evaluated by the method suggested by Schleifer.¹⁸ In the presence of a cellular marrow with increased or normal frequency of erythroblastic islands, as determined by examination of the histologic pattern, a significantly lowered M:E ratio may be taken as a rough measure of the degree of acceleration or increase of erythropoiesis.

In the control series the incidences of plurinuclear erythroblasts vary from 1.0 to 5.1 per 1,000 uninuclear erythroblasts. The myeloid:erythroid ratios vary from 2:1 to 3:1. On the basis of the normal material available at present, it must be concluded that a myeloid:erythroid ratio significantly lower than 2:1 and an incidence of plurinuclear erythroblasts significantly greater than 5.1 per 1,000 uninuclear erythroblasts are to be regarded as abnormal. Furthermore, the presence of an appreciable number of pluripolar mitoses is abnormal, as indicated by the fact that in a total of 53,167 erythroblasts in eight normal persons, not a single example of pluripolar mitosis was seen. In addition, no examples of high plurinuclearity, that is, cells with more than two nuclei were encountered in normal marrows. Finally, the differential distribution of the plurinuclear erythroblasts, represented in Table II, reveals the relative rarity of plurinuclear pronormoblasts and plurinuclear orthochromic normoblasts. It is noteworthy that the differential distribution of the plurinuclear cells is similar to that of the normoblasts in general in normal individuals.

TABLE II. DIFFERENTIAL DISTRIBUTION OF PLURINUCLEAR AND UNICLEAR NORMOBLASTS IN NORMAL HUMAN STERNAL MARROW

	PNE	UNE
Total cells examined	167	2000
Pronormoblasts	1%	2%
Basophilic normoblasts	24%	11%
Polychromatophilic normoblasts	74%	86%
Orthochromic normoblasts	1%	1%

PNE, plurinuclear erythroblasts.

UNE, uninuclear erythroblasts.

One must conclude that the alleged rarity of pluripolar mitoses among erythroblasts in normal sternal marrow is an actuality, whereas the alleged rarity of plurinuclear erythroblasts must be explained on the basis of their having been overlooked in routine examination of marrow smears, due to their relatively small incidence.

INCIDENCE OF PLURINUCLEAR ERYTHROBLASTS AND PLURIPOLAR MITOSES AMONG ERYTHROBLASTS IN PATHOLOGIC HUMAN STERNAL MARROWS

Limarzi and Levinson present data indicating the incidence of cells classified as atypical erythroid cells, which we assume to represent the giant erythroblasts in their material, as 63.8 per 1,000 typical erythroblasts.⁶ Only one study was available during life. Schwarz does not offer statistical data regarding the incidence of plurinuclear cells. It is stated, however, that one case of myeloblastic leukemia was "quite outstanding in the degree and the frequency of the abnormality in question."²⁰ Schleicher gave the ratio of giant orthochromic erythroblasts to late pronormoblasts as 4 to 1 in one case, and he recorded the ratio of giant orthochromic erythroblasts to early and late basophilic erythroid cells as 3 to 1 in his second case. He did not discuss the significance of these ratios.

The incidences of plurinuclear erythroblasts in our pathologic marrows are shown in Table III. They vary from 16.0 to 159.6 per 1,000 uninuclear erythroblasts in the initial studies. Obviously, these data do not reflect the actual incidence of plurinuclear cells in pathologic marrows, since no attempt was made to survey all of our material. It can be stated, however, that rapid scanning of several slides with the low-power objective suffices for the discovery of such cells in bone marrow concentrate smears in which their frequency is in the neighborhood of 30 per thousand erythroblasts. They are easily noticed because of their large size. Plurinuclear erythroblasts easily may be overlooked in normal marrow smears because of their infrequent occurrence. On the other hand, it is difficult to understand how plurinuclear erythroblasts can be overlooked in pathologic marrows, especially in instances of increased erythropoiesis, since they are frequently present in our material and that of others.^{13, 20} In Cases 1, 2, and 3 with incidences of 159.6, 99.2, and 52.8, respectively, the cells were so numerous that the smears presented a striking pathologic picture on

*Calculated from their data.

first inspection. The pathologic marrows also afforded excellent opportunities for examination of pluripolar mitoses (see individual case reports).

ON THE QUESTION OF THE TERMINAL NATURE OF THE PHENOMENON OF PLURINUCLEAR OR ERYTHROBLASTS

Schleicher's observation of two cases with giant orthochromic erythroblasts in patients with terminal illnesses, and Limarzi and Levinson's single case with terminal disease cannot be accepted as evidence of the terminal nature of the findings, since our series includes several cases showing an abnormal incidence of plurinuclear erythroblasts with clinical recovery (Table III). It is essential that serial marrow studies be made on patients exhibiting the change so that remission from the underlying clinical disease with a concomitant disappearance of the condition of plurinuclearity may not be overlooked.

ON THE QUESTION OF IRREVERSIBILITY AND CANCEROUS NATURE OF THE CHANGES

Some authors^{13, 14} have considered the phenomenon under discussion to represent an irreversible change in the marrow or an indication of a defunct reticulum. As has been pointed out, the marrow pattern, in so far as erythropoiesis is concerned, may revert to normal after exhibiting a temporary period during which plurinuclear cells may be formed. The data already presented are evidence in favor of the concept of the reversibility of the lesion. The belief that the lesion is of cancerous nature¹⁵ is partly based on the assumption that the changes are irreversible. Furthermore, it has been stated that bipolar mitosis and multipolar mitosis of erythroid cells in the same marrow is an unusual finding in the adult.¹⁵ Our data do not conform to either of these assumptions. According to Schwarz, pluripolar mitosis does not represent a more fertile type of regeneration, as suggested by Limarzi, Jones, and Levinson,¹⁴ nor is his material in accord with a biologic transformation akin to neoplastic deviation as assumed by these authors.

Although Schwarz does not present serial marrow studies on his cases showing plurinuclear erythroblasts, he concludes, largely on the basis of experimental evidence, that once normal conditions are restored the plurinuclear erythroblast tends to divide into as many daughter cells as there were nuclei formed by the preceding karyokinesis. The experimental work of Chambers,⁴ cited by Schwarz as evidence for the reversibility of the phenomenon of suppressed cytokinesis, is based on the observations of sea-urchin eggs subjected to hypertonic sea water and later replaced in sea water, late amphister eggs placed in 2½ per cent ether solution in sea water and replaced within five minutes in sea water, late amphister eggs subjected to contact with 1½ to 2 per cent ether solutions in sea water or hypotonic solutions, and amphister eggs subjected to mechanical agitation. The following case reports are presented as evidence of reversibility of the changes under question in patients with clinical disease.

CASE REPORTS

CASE 1.—A white woman, aged 65 years, stated that she felt well until December, 1944, when she began to experience weakness, malaise, dyspnea, and weight loss. The only sig-

nificant findings on physical examination were enlarged liver and spleen. The edge of the liver was 5 cm. below the costal margin and the inferior border of the spleen extended below the umbilicus. On March 8, 1946, the initial blood studies showed: erythrocytes, 1.84 millions per cubic millimeter; hemoglobin, 7.7 grams per cent; reticulocytes, 1.5 per cent; leucocytes, 1,900 per cubic millimeter; platelets, 61,000 per cubic millimeter; mean corpuscular volume, 109 cubic microns; mean corpuscular hemoglobin, 42 micromicrograms. The differential distribution of the leucocytes was: band form neutrophils, 19 per cent; polymorphonuclear neutrophils, 21 per cent; monocytes, 23 per cent; lymphocytes, 38 per cent.

The bone marrow study revealed hypercellular marrow with marked increase in the frequency of erythroblastic islands as observed by inspection of gross marrow units (Schleicher's). The myeloid:erythroid ratio was 1:1. Erythropoiesis was atypical, characterized by the presence of dysplastic erythroblasts having a superficial resemblance to megaloblasts because of their large size and relatively vesicular chromatin networks in the nuclei. There were also numerous plurinuclear erythroblasts which were present in a frequency of 159.6 per thousand uninuclear erythroblasts (Table III). Myeloid leucopoiesis was relatively reduced, with band form neutrophils predominating. Megakaryocytopoiesis was reduced. There were 49 per cent lymphocytes. Numerous monocytoid cells recently derived from reticulum appeared in isolated instances and in syncytial masses with two to four nuclei. These resembled cells the author had previously encountered in imprints of lymph nodes from cases of reticulum cell type of lymphoblastoma, and they recall Schleicher's description of monocytoid reticulum cells in his Case 1, proved at autopsy to be reticulum cell sarcoma. The blood and marrow findings were summarized as macrocytic hyperchromic anemia, neutropenia, thrombocytopenia, probable reticulum cell type of lymphoblastoma with involvement of bone marrow, liver, and spleen, and accelerated dysplastic erythropoiesis with increased frequency of plurinuclear erythroblasts. In addition, there were numerous examples of pluripolar mitoses among erythroblasts (Plates I and II). Their incidence was 9.6 per thousand erythroblasts.

The patient received transfusions, vitamin B₁₂, and oral folic acid. After twenty days, the appetite had returned and she began to gain weight and strength rapidly. On May 12, 1946, the blood study showed: erythrocytes, 2.11 millions per cubic millimeter; hemoglobin, 5.5 grams per cent; reticulocytes, 15.8 per cent; leucocytes, 3,000 per cubic millimeter; mean corpuscular volume, 107 cubic microns; mean corpuscular hemoglobin, 26 micromicrograms.

The bone marrow study revealed hypercellular marrow, as previously. The myeloid:erythroid ratio was 1:1. The most significant change from the previous myelogram was a reduction in the incidence of plurinuclear erythroblasts from 159.6 to 13.8 per 1,000 uninuclear erythroblasts (Table III). There were only 2.4 per 1,000 pluripolar mitoses in the second study.

Comment.—The case demonstrates the variability of the frequency of plurinuclear erythroblasts and pluripolar mitoses in a single patient. It is noteworthy that the reduction in their incidences occurred with improvement of the clinical condition of the patient and a reduction of the severity of the anemia. To be sure, the second study revealed that the changes were still present in a degree significantly greater than normal; but in view of the probability that the patient has a neoplastic disease affecting the liver, spleen, and bone marrow, the failure of the abnormality of erythropoiesis to disappear completely is to be expected. Furthermore, erythropoiesis was still accelerated at the second examination.

CASE 2.—A 52-year-old white man was admitted to the hospital June 3, 1946, with a history of dyspnea, weakness, tarry stools, and occasional vomiting. Three weeks before admission he drank an unknown quantity (approximately 2 pints) of a commercial shellac solvent. The significant findings were marked pallor, firm and barely palpable liver, and severe thrombosed and bleeding hemorrhoids. The serologic tests for syphilis were positive.

The stools revealed traces to 4 plus occult blood during the entire hospital stay. Repeated studies for ova and parasites gave negative results. Two x-ray examinations of the entire gastrointestinal tract failed to reveal any sources of the blood in the stools. The only known sources were hemorrhoids, which were very prominent. The patient refused surgical treatment. Biopsy of the liver showed a normal histologic structure. The initial blood study showed: erythrocytes, 1.30 millions per cubic millimeter; hemoglobin, 2.9 grams per cent; reticulocytes, 7.2 per cent; leucocytes, 6,500 per cubic millimeter; platelets, 100,000 per cubic millimeter; mean corpuscular volume, 77 cubic microns; mean corpuscular hemoglobin, 22 micromicrograms.

The bone marrow study revealed hypercellular marrow with marked increase of erythropoiesis and a myeloid:erythroid ratio of 1:1. Erythropoiesis was normoblastic. There were 99.2 plurinuclear erythroblasts and 3.1 pluripolar mitoses per 1,000 uninuclear normoblasts (Table III and Plates I and II). Myeloid leucopoiesis and megakaryocytopoiesis were unaltered. There were 13 per cent lymphocytes. The blood and marrow findings were summarized as microcytic hypochromic anemia, neutropenia, thrombocytopenia, and accelerated normoblastic erythropoiesis with increased frequency of plurinuclear erythroblasts.

During a period of observation from June 6 to 26, 1946, iron therapy and transfusions were withheld. On June 26 the blood study showed: erythrocytes, 1.40 millions per cubic millimeter.

The bone marrow findings were similar to those of the first study, with the exception that the incidence of plurinuclear cells had dropped from 99.2 to within a normal level of 5.4 per 1,000 uninuclear erythroblasts (Table III). No pluripolar mitoses were seen among 5,000 erythroblasts.

Comment.—The case illustrates a remission from the condition of atypical plurinuclear erythropoiesis, in spite of the continued presence of severe anemia and accelerated erythropoiesis.

CASE 3.—A 62-year-old white man with idiopathic pernicious anemia experienced an hematologic remission as a result of folic acid therapy. The initial blood study showed: erythrocytes, 730,000 per cubic millimeter; hemoglobin, 2.7 grams per cent; reticulocytes, 1.7 per cent; leucocytes, 5,800 per cubic millimeter; platelets, 16,000 per cubic millimeter; mean corpuscular volume, 122 cubic microns; mean corpuscular hemoglobin, 38 micromicrograms.

The bone marrow study revealed hypercellular marrow with increased erythropoiesis of megaloblastic type and a myeloid:erythroid ratio of 1:2. There were 52.8 plurinuclear erythroblasts and 2.8 pluripolar mitoses per 1,000 uninuclear erythroblasts (Table III). Only an occasional plurinuclear erythroblast had normoblastic character; the remaining plurinuclear erythroblasts were megaloblastic. Myeloid leucopoiesis revealed changes characteristic of antipernicious anemia principle deficiency.¹⁰ Megakaryocytopoiesis was reduced.

At the time of the second marrow study, the blood showed: erythrocytes, 3.63 millions per cubic millimeter; hemoglobin, 10.7 grams per cent. The second bone marrow study revealed cellular marrow with slightly increased erythropoiesis and a myeloid:erythroid ratio within the normal range (2:1). Erythropoiesis was entirely normoblastic. The incidence of plurinuclear erythroblasts had dropped from 52.8 to 4.4 per 1,000 uninuclear erythroblasts (Table III). Only one pluripolar mitosis was found among 10,000 erythroblasts.

Comment.—The case illustrates the complete remission of the condition of excessive plurinuclearity and pluripolarity among erythroblasts in megaloblastic marrow as a result of specific therapy.

CASE 4.—A 54-year-old white man was admitted because of mild acute hepatitis. Serologic tests for leptospira were negative. Various liver function tests revealed only slight disturbances. The initial blood study on Oct. 16, 1946, showed: erythrocytes, 3.17 millions per cubic millimeter; hemoglobin, 11.6 grams per cent; reticulocytes, 6.6 per cent; leucocytes, 5,500 per cubic millimeter; platelets, 300,000 per cubic millimeter; mean corpuscular volume, 100 cubic microns; mean corpuscular hemoglobin, 37 micromicrograms.

The bone marrow study revealed slightly hypercellular marrow with increased erythropoiesis and a myeloid:erythroid ratio of 1:1. Erythropoiesis was normoblastic. There were 35.8 plurinuclear erythroblasts and 1.0 pluripolar mitoses per 1,000 uninuclear erythroblasts (Table III). The blood and marrow findings were summarized as macrocytic normochromic anemia and accelerated normoblastic erythropoiesis with increased frequency of plurinuclear erythroblasts.

The icterus cleared and the patient remained asymptomatic. A final blood study on Nov. 12, 1946, showed: erythrocytes, 4.00 millions per cubic millimeter; hemoglobin, 13.3 grams per cent; leucocytes, 7,150 per cubic millimeter.

The second bone marrow study revealed approximately normal cellularity and a myeloid:erythroid ratio of 3:1. The only significant finding in the myelogram was evidence of a decrease of the incidence of plurinuclear erythroblasts from 35.8 to 6.0 per 1,000 uninuclear cells (Table III). One pluripolar mitosis was seen.

Comment.—The case illustrates that the temporary condition of excessive plurinuclearity of erythroblasts may occur in relatively mild clinical disease.

CASE 5.—A white woman, aged 18 years, with congenital hemolytic anemia, was admitted because of an acute hemolytic episode. The initial blood study on Nov. 3, 1943, showed: erythrocytes, 1.13 millions per cubic millimeter; hemoglobin, 4.6 grams per cent; reticulocytes, 13 per cent; leucocytes, 26,400; platelets, 400,000 per cubic millimeter; mean corpuscular volume, 92 cubic microns; mean corpuscular hemoglobin, 41 micromicrograms. There were 60 normoblasts per 100 leucocytes. The erythrocytes were deeply staining cells of small diameter (spherocytes).

The bone marrow study revealed hyperplastic marrow with a myeloid:erythroid ratio of 1:2. Erythropoiesis was normoblastic. There were 32.0 plurinuclear erythroblasts and 1.8 pluripolar mitoses per 1,000 uninuclear erythroblasts (Table III). The blood and marrow findings were summarized as normocytic normochromic anemia with spherocytosis, normoblastic crisis, neutrophilic leucocytosis, and accelerated normoblastic erythropoiesis with increased frequency of plurinuclear erythroblasts. Splenectomy was performed Nov. 11, 1943, without complications.

At the time of the second marrow study on Nov. 23, 1943, the blood showed: erythrocytes, 4.33 millions per cubic millimeter; hemoglobin, 12.4 grams per cent. The second marrow study revealed hypercellular marrow with a myeloid:erythroid ratio of 7:1, revealing that the chief cause of the hypercellularity was increased leucopoiesis. The incidence of plurinuclear erythroblasts had fallen from 32.0 to 5.2 per 1,000 uninuclear erythroblasts (Table III), and only one pluripolar mitosis was seen among 7,000 erythroblasts.

Comment.—The case illustrates the remission of the condition of excessive plurinuclearity after removal of an important factor (hypersplenism) in the pathogenesis of the clinical disease.

CASE 6.—A 32-year-old white woman was admitted with cirrhosis of the liver, proved by biopsy. The initial blood study on June 16, 1946, showed: erythrocytes, 2.52 millions per cubic millimeter; hemoglobin, 9.4 grams per cent; reticulocytes, 2.4 per cent; leucocytes, 10,550 per cubic millimeter; platelets, 126,000 per cubic millimeter; mean corpuscular volume, 135 cubic microns; mean corpuscular hemoglobin, 37 micromicrograms.

The bone marrow study revealed hyperplastic marrow with a myeloid:erythroid ratio of 1:1. Erythropoiesis was normoblastic, with an incidence of 23.0 plurinuclear erythroblasts and 2.8 pluripolar mitoses per 1,000 uninuclear erythroblasts (Table III). The blood and marrow studies were summarized as macrocytic normochromic anemia, thrombocytopenia, and accelerated normoblastic erythropoiesis with increased frequency of plurinuclear erythroblasts.

The patient received various forms of therapy, following which her clinical condition improved. Four days before her discharge the blood study showed: erythrocytes, 3.88 millions per cubic millimeter; hemoglobin, 9.2 grams per cent.

The second marrow study revealed slightly hypercellular marrow without increased incidence of plurinuclear erythroblasts, which were now 6.0 per 1,000 uninuclear erythroblasts. There was only one pluripolar mitosis in approximately 12,500 erythroblasts.

Comment.—The case illustrates the disappearance of excessive plurinuclearity in a patient with a permanent lesion such as cirrhosis of the liver, concomitant with clinical improvement.

CASE 7.—A 27-year-old white man was admitted with monocytic leucemia. The initial blood studies showed: erythrocytes, 2.00 millions per cubic millimeter; hemoglobin, 4.5 grams per cent; reticulocytes, 0.1 per cent; leucocytes, 15,000; platelets, 30,000 per cubic millimeter; mean corpuscular volume, 75 cubic microns; mean corpuscular hemoglobin, 22.5 micromicrograms. The differential distribution of the leucocytes was: myeloblasts, 2 per cent; promyelocytes, 1 per cent; myelocytes, 1 per cent; metamyelocytes, 3 per cent; band form neutrophils 26 per cent; polymorphonuclear neutrophils, 14 per cent; eosinophile promyelocytes, 1 per cent; eosinophiles, $\frac{1}{2}$ per cent; monocytes and immature monocytoïd cells, 26 per cent; lymphocytes, 25 per cent; plasma cells, $\frac{1}{2}$ per cent; megakaryocytic nuclei, 1 per cent; atypical polychromatophilic erythroblasts, 3 per 100 leucocytes. There were numerous giant platelets.

The bone marrow study revealed hyperplastic marrow with a myeloid:erythroid ratio of 2:1. Erythropoiesis was of the dysplastic type, resembling that seen in Case 1. There were 18.8 plurinuclear erythroblasts, and an occasional pluripolar mitosis per 1,000 uninuclear erythroblasts (Table III). Myeloid leucopoiesis was altered because of the development of monocytoïd stem cells and monocytes, which comprised a total of 25 per cent of the nucleated cells. The hematologic findings were diagnostic of monocytic leucemia, Naegeli type. The patient received various forms of therapy, without effect.

Five months later, the marrow study revealed findings similar to those seen in the initial examination, with the exception that atypical stem cells and monocytoïd stem cells were more numerous and that the incidence of plurinuclear erythroblasts had increased slightly from 18.8 to 22.0 per 1,000 uninuclear erythroblasts.

Comment.—This case is included by way of contrast with the others, since it illustrates the persistence of the plurinuclear trait in a patient whose clinical condition became worse during the period of observation.

CASE 8.—A 23-year-old white woman with idiopathic thromboeytopenic purpura was admitted to the hospital because of approximately five months of purpura and bleeding from mouth and vagina. The initial blood study showed: erythrocytes, 2.26 millions per cubic millimeter; hemoglobin, 6.7 grams per cent; reticulocytes, 24.5 per cent; leucocytes, 12,400 per cubic millimeter; platelets, 1,900 per cubic millimeter; mean corpuscular volume, 93 cubic microns; mean corpuscular hemoglobin, 29.6 micromicrograms. There were 4 normoblasts per 100 leucocytes.

The bone marrow study revealed hyperplastic marrow with a myeloid:erythroid ratio of 1:2. Erythrocytogenesis was normoblastic, with 16.0 plurinuclear erythroblasts and 2.2 pluripolar mitoses per 1,000 uninuclear erythroblasts (Table III). Megakaryocyto-genesis was normal quantitatively. Splenectomy was performed without complications on Oct. 4, 1946.

All hemorrhagic and purpuric tendencies had disappeared by the fourth postoperative day. On Nov. 11, 1946, the blood showed: erythrocytes, 4.42 millions per cubic millimeter; platelets, 90,000 per cubic millimeter.

The second marrow study revealed approximately normal cellularity, with a myeloid:erythroid ratio of 2:1. The only other significant change in the myelogram was the appearance of evidence that the incidence of plurinuclear erythroblasts had dropped from 16.0 to 3.8 per 1,000 uninuclear erythroblasts. One pluripolar mitosis was seen among 5,000 erythroblasts.

Comment.—The case is an additional example of the disappearance of the condition of excessive plurinuclearity of erythroblasts concomitant with clinical and hematologic improvement following the removal of one of the important factors (hypersplenism) in the pathogenesis of the associated clinical disease.

DISCUSSION

The case reports presented include examples illustrating the temporary or reversible nature of the condition of plurinuclearity of erythroblasts and of pluripolarity of mitoses among erythroblasts in patients with either mild or serious clinical diseases (Cases 2, 3, 4, 5, 6, 8). The importance of such findings is obvious when applied to the concept of a cancerous nature of the changes. The fact that plurinuclear erythroblasts are present in normal marrows is additional evidence against their cancerous nature. Furthermore, the differential distributions and morphologic characters of the plurinuclear cells are remarkably similar to those of the multinuclear cells in the pathologic as well as the normal cases. This is suggestive of the action of the etiologic factors on any types of erythroblasts which are present at the time such factors come into play. Thus, the plurinuclear forms under question may be regarded as variants of the prevailing types of erythroblasts and not as members of a new genetic line of cells. In Cases 1 and 7 (lymphoblastoma and leucemia) with dysplastic erythropoiesis, the atypical giant plurinuclear cells could easily have been interpreted as representatives of a new cell line. However, the morphologic forms of the plurinuclear cells appeared to be modifications of the prevailing erythroblasts, readily explained by suppression of cytokinesis alone. It cannot be argued that because two of our cases occurred in association with malignant disease (Case 1, lymphoblastoma, and Case 2, leucemia), plurinuclearity of erythroblasts is related to malignant proliferation of cells in the bone marrow, since none of the other cases had any relationship to malignant disease. We have recently studied a case of polycythemia vera of several years' duration, now terminating as myelogenous leucemia. The bone marrow in this patient reveals only a normal incidence of plurinuclear cells.

A patient with chronic microcytic hypochromic anemia (Case 2) revealed a marked decrease in the incidence of plurinuclear erythroblasts to normal levels in spite of absence of clinical or hematologic improvement. While in most cases excessive plurinuclearity among erythroblasts was associated with accelerated erythropoiesis, it may be absent, or it may disappear, as in Case 2 in which a possible toxic agent (ingested shellac solvent) may have played an etiologic role.

The occurrence of the phenomena in relation to a progressive unfavorable course in patients who ultimately succumb to their clinical disease is not acceptable evidence in favor of an irreversible change. Indeed, the apparent nonreversibility is the result, not the cause, of the underlying clinical condition. Additional data may determine a range of incidences of plurinuclearity which is indicative of nonreversibility, but the present material shows that incidences of 99.2 and 159.6 per 1,000 are below such limits.

The present study does not disclose the action of factors common to all the cases. It is possible that when more cases illustrating plurinuclearity of high incidence are accumulated, such factors may be discovered. At any rate, the changes we have described, which involve suppression of cytokinesis without interference with maturation or karyokinesis, are not specific for any type or condition of erythropoiesis.

SUMMARY

The incidences of plurinuclearity and pluripolar mitoses among erythroblasts in sternal marrows of eight normal individuals have been determined to be 1.0 to 5.1, and less than 1.0 per 1,000 uninuclear erythroblasts, respectively.

The incidences of such changes in eight pathologic cases have been shown.

The reversible nature of the phenomena of plurinuclearity and pluripolarity among erythroblasts of normoblastic, dysplastic, and megaloblastic types has been demonstrated.

The significance of the findings has been discussed.

ENHANCEMENT OF BLOOD LEVELS BY CARONAMIDE DURING INTRAMUSCULAR ADMINISTRATION OF PENICILLIN

ALBERT O. SEELER, M.D., CLARE WILCOX, AND MAXWELL FINLAND, M.D.
BOSTON, MASS.

THE rapidity with which penicillin disappears from the blood and is excreted in the urine was recognized early in the study of this antibiotic.^{1, 2} Rammelkamp and Bradley,³ on the basis of data showing that diodrast blocked the renal excretion of penicillin, suggested that penicillin was probably excreted by a tubular mechanism. Studies by Rantz and Kirby⁴ demonstrated that in afebrile patients 750 to 1,120 ml. of plasma could be cleared of penicillin per minute. This was proof of the tubular excretion of penicillin since glomerular filtration could account for only a small fraction of such a large rate of excretion.

The possibility of prolonging the blood levels of penicillin by blocking the excretory channel has received considerable attention. Following the observation of Rammelkamp and Bradley referred to in the preceding paragraph, Beyer and associates⁵⁻⁷ succeeded in decreasing the rate of excretion of penicillin by the use of para-aminohippuric acid. Several reports have appeared in which para-aminohippuric acid has been used with apparent success in clinical penicillin therapy.⁷⁻¹⁰ Unfortunately, large amounts of diodrast or para-aminohippuric acid must be given to slow the excretion of penicillin significantly since these agents themselves are rapidly excreted by the renal tubules. The fact that both diodrast and para-aminohippuric acid must be administered intravenously is also a serious handicap to their general use.

Bronfenbrenner and Favour¹¹ found that the administration of 2.5 Gm. of benzoic acid by mouth every four hours to patients on an unrestricted diet may double the penicillin levels, and that the administration of this amount of benzoic acid to patients in whom fluid and salt intake is restricted may result in an even greater increase in the penicillin blood concentrations.

Recently Beyer¹² reported that the excretion of penicillin could be reversibly inhibited by 4'-carboxyphenylmethanesulfonanilide, a compound synthesized by Sprague and co-workers and called caronamide.¹³ According to Beyer and co-workers,¹⁴ this compound, while capable of blocking the tubular excretion of penicillin, is not itself subject to a significant degree of tubular excretion. Toxicity studies¹⁵ showed caronamide to have an acute oral LD₅₀

of 1,405 mg. per kilogram for mice; 1,320 mg. per kilogram for rabbits; and 1,575 mg. per kilogram for dogs. No evidence of histologic damage or hematologic disturbances was observed in rats given 0.5 Gm. per kilogram of caronamide daily for four weeks or in dogs receiving daily doses as high as 1.5 Gm. per kilogram for the same length of time. Verwey and Miller¹⁶ found that caronamide administered orally increased the effectiveness of a given intramuscular dose of penicillin against experimental infections in mice. They believe that the enhancement of penicillin activity by caronamide is due to the effect of the agent on the penicillin concentrations in the body rather than to any synergistic action.

Rapoport and associates¹⁷ studied the toxicity of caronamide and its effectiveness in inhibiting penicillin excretion in fifteen children. In none of their patients did the drug have to be withdrawn because of toxicity when administered in oral doses of 0.1 to 0.4 Gm. per kilogram per day for one or two weeks. Three of their patients developed a rash. They found that 0.2 Gm. per kilogram per day of caronamide given orally increased the plasma levels of penicillin significantly, and that 0.4 Gm. per kilogram per day resulted in a marked rise in penicillin levels. No irreversible changes in glomerular filtration, renal plasma flow, maximum tubular excretory capacity (P. A. II. Tm), or maximum reabsorptive capacity (glucose Tm) were found.

Crosson and co-workers¹⁸ in preliminary studies in adults found that 2 Gm. of caronamide given every four hours enhanced penicillin blood levels when the penicillin was given orally in a dose of 100,000 units or intramuscularly in a dose of 50,000 units. They found that administration of 1 Gm. of caronamide every two hours in similar subjects had little effect on the penicillin levels, while 1.5 Gm. every three hours definitely increased the penicillin levels. It is of interest that in the only patient to whom they gave 100,000 units of penicillin intramuscularly every four hours they failed to obtain increased penicillin levels with 2 Gm. of caronamide every four hours.

These findings seemed sufficiently encouraging to justify further study of caronamide, particularly in relation to the use of large doses of penicillin, with a view to the possibility of decreasing the frequency of injections while maintaining significant concentrations in the blood.

MATERIALS AND METHODS

Choice of Subjects.—The subjects were male hospital patients who were given penicillin, some of them during an acute illness but most of them during convalescence from various infections. Since it is known that advanced renal disease may interfere with penicillin excretion,² no patient was chosen in whom there was impairment of renal function as judged by the inability to concentrate urine or to maintain a normal concentration of nonprotein nitrogen in the blood. Otherwise the subjects were selected without regard to their disease. The patients were given the usual hospital diet and no restrictions were placed on their fluid or salt intake. Urine analyses and blood nonprotein nitrogen determinations were done before and during the caronamide administration.

Penicillin and Caronamide Administration.—All of the penicillin doses were given intramuscularly at eight-hour intervals. Crystalline sodium penicillin G, as available commercially, was used throughout and was given as a solution in normal saline in a concentration of 100,000 units per milliliter. The caronamide was supplied in 0.5 Gm. tablets and was given in various doses by mouth every four hours so that every other dose was given at the time of an intramuscular penicillin injection.

In the studies on the effect of caronamide on penicillin levels, the subjects were kept on a constant dosage of 100,000 units of penicillin every eight hours throughout the time when the caronamide was given, and for at least two days before the first dose, and for two, or more often three, days after the last dose of caronamide. The caronamide was usually given for twenty-four hours, and in a few instances during a forty-eight hour period, in order to permit the drug to reach an equilibrium in the body fluids.

Penicillin Blood Levels.—Blood for penicillin levels was obtained during the eight-hour intervals after the last dose of penicillin given during the period of caronamide administration. Two control series of blood were also obtained during similar eight-hour periods, one series just prior to the first dose, and the other two or three days after the last dose of caronamide. The blood was obtained just before and one-half, four, six, and eight hours after the penicillin injection. The first blood in each series was obtained, in each instance, at about 9 A.M. The concentrations of penicillin were determined on citrated plasma by the serial dilution method of Rammelkamp,¹⁹ modified only by the use of 0.5 ml. amounts of the plasma dilutions.*

RESULTS

Effect of 2 Gm. of Caronamide Every Four Hours.—The plasma penicillin levels obtained in twelve subjects before, during, and after a period when caronamide was given in doses of 2 Gm. every four hours are shown in Table I. One-half of the subjects were under 60 years of age; in none of them was there any significant difference in the levels obtained while they received caronamide as compared with the control periods before and after the caronamide administration.

A marked effect from the caronamide was obtained in five of the six subjects over 60 years of age. The effect varied considerably in the different individuals. The levels obtained one-half hour after the dose of penicillin, which probably represent the maximum attained in most patients, were essentially the same (considering the limitations of the method) during the control periods and during the caronamide administration. At four and six hours after the penicillin injections, the levels obtained during the caronamide ingestion ranged from four to sixteen times those found during the control periods. At the beginning and end of the eight-hour interval, the levels in the

*The end point was taken as the dilution in which there was no visible growth of the test organism in broth and on subculture to blood agar. In the occasional serum in which there was no visible growth in the broth and one or more colonies of streptococci developed on the blood agar, the level was taken as the mean of that concentration and the one in which no growth occurred on subculture.

*All values <0.01 unit are listed as 0.

same five subjects ranged from 0.03 to 0.5 unit per milliliter of plasma during the caronamide administration and from < 0.01 to 0.06 unit during the control periods. The average increase in the levels for all the six subjects over 60 years of age was about six- and ninefold at four and six hours, respectively. The average level at the beginning and end of the eight-hour interval during caronamide administration was 0.20 and 0.23 unit per milliliter, respectively, as compared with 0.02 unit or less at the same times during the control periods.

Effect of 3 Gm. of Caronamide Every Four Hours in Persons Under 60 Years of Age.—The plasma penicillin levels obtained in four subjects under 60 years of age (Cases 13 to 16) who were given 3 Gm. of caronamide every four hours are shown in the upper part of Table II. In none of these four subjects was there any appreciable effect from the caronamide, the levels throughout the eight-hour period being essentially the same while the drug was given and during the control periods.

Effect of 4 Gm. of Caronamide Every Four Hours in Subjects Under 60 Years of Age.—Ten patients under 60 years of age (Cases 17 to 26) were given 4 Gm. of caronamide every four hours. The penicillin levels resulting from an intramuscular dose of 100,000 units of penicillin in these subjects before, during, and after the caronamide administration are also shown in Table II. An appreciable effect was obtained from the caronamide in every one of these ten subjects, but the effect varied widely in the different individuals. The levels obtained at one-half hour were higher during the caronamide administration in eight of the ten subjects. At four hours the levels during the caronamide period were from four to thirty-two times higher than at the same time during the control periods. At six hours only one subject failed to show an increased level; in the other nine the concentrations of penicillin were two to sixteen times higher during the caronamide administration. Demonstrable levels were obtained in most of the subjects at the end of eight hours (that is, just before the penicillin dose) while they were receiving caronamide but not during the control periods.

For the ten subjects under 60 years of age, the average plasma penicillin level eight hours after an intramuscular dose of 100,000 units of penicillin (or just before such a dose) during the oral administration of 4 Gm. of caronamide every four hours was 0.03 unit per milliliter. At six hours the average level was 0.08 unit per milliliter. Practically none was demonstrable at these times during the control periods in the same subjects. The average levels of penicillin one-half hour and four hours after the penicillin injections were, respectively, about two and ten times higher during the caronamide administration than they were during the control periods.

Effect of Increasing the Dose of Penicillin.—An attempt was made to estimate roughly the intramuscular dose of penicillin which, given at eight-hour intervals, would be required to maintain blood concentrations (particularly during the latter half of that interval) approximating those that resulted from injections of 100,000 units every eight hours during the oral administration of the minimum effective amounts of caronamide. For that purpose another group of subjects were given intramuscular doses of 100,000 units every eight

* All values <0.01 unit are listed as 0.

hours for one or two days. This was followed by 200,000 units every eight hours and finally 300,000 units every eight hours for similar periods. A series of blood penicillin levels were obtained during an eight-hour interval on each dose, just as in the previous studies.

Since it was shown that the blood levels on doses of 100,000 units were much better sustained in patients over 60 years of age than in those under

60 years, subjects of both age groups were chosen. The plasma penicillin levels obtained on these three dose levels in six subjects under 60 years and in a similar number of patients over 60 years of age are shown in Table III.

The expected increases in the penicillin levels with the progressive increases in the dose were noted, but there were considerable individual variations. Although marked differences were noted between the height of the levels obtained with any given dose in the two age groups, the increases in levels resulting from increasing the size of the dose were quite similar in both age groups.

Comparison of Effects Obtained From Caronamide With Those Obtained From Increasing the Dose of Penicillin.—In order to compare the effect of caronamide with that obtainable by increasing the dose of penicillin, it would be desirable to carry out all of the studies in the same subjects. This, however, was not feasible. A rough estimate of the comparative effects may nevertheless be made from the data already presented. For that purpose it is best to consider the subjects in the two age groups (that is, those under 60 years of age and those over 60 years of age) separately.

The comparison in the subjects over 60 years of age may be made from the data shown for Cases 7 to 12 in Table I and for Cases 33 to 38 in Table II, particularly from the average values given in these tables. A similar comparison in the subjects under 60 years of age may be made from the levels shown in Table II (Cases 17 to 26) for the effects of 4 Gm. of caronamide and those given for Cases 27 to 32 in Table III. The average values for these groups are shown graphically in Fig. 1. In this figure the averages for the control levels obtained before and after caronamide are included in a single curve.

The curves representing the average levels following increasing doses of penicillin were obtained in the same patients. Those representing the effect of caronamide, however, are averages from other groups of patients. It should be noted that all of the latter patients had been on caronamide therapy for at least sixteen hours before the penicillin levels were determined so that there were appreciable penicillin serum concentrations at zero hour on these curves.

The difference in the declining slope of the curves between the patients under and those over 60 years of age is striking. In the older patients a significant concentration of penicillin persisted in the serum eight hours after the injection of 100,000 units, even when caronamide was not given, whereas in the younger subjects little or no penicillin was detectable six hours after such an injection. Increasing the dose of penicillin altered the height of the curves to a similar extent in both age groups but did not significantly alter the slope of these curves. The caronamide, on the other hand, increased the peak penicillin levels to some extent, but its effect on slowing the rate of fall of the plasma penicillin concentrations was striking. Except at the time of the peaks, the patients receiving the caronamide and 100,000 units of penicillin had significantly higher levels than those receiving 300,000 units of penicillin without caronamide. This difference was greatest in both age groups six

hours after the penicillin injection. The levels obtained with 100,000 units of penicillin (without caronamide) were comparable within each age group in both series of studies.

Toxicity.—There was no clinical or laboratory evidence of toxicity from the caronamide in any of the subjects. In no instance was crystalluria, hematuria, or albuminuria observed which could be attributed to caronamide. No

Fig. 1.—Enhancement of plasma levels by caronamide during intramuscular administration of 100,000 units of penicillin every eight hours; comparison with effect of increasing the dose in subjects within the same age group.

significant increase in the level of blood nonprotein nitrogen occurred. Furthermore, the reducing substance reported by Beyer and co-workers¹⁵ as occurring in the urine of animals during administration of caronamide in large doses was not encountered in any of these cases. The findings in the present cases, however, must be interpreted in the light of the brief period during which the caronamide was given.

COMMENT

These studies confirm the findings previously mentioned and show conclusively that caronamide administered by mouth in adequate doses signifi-

cantly enhances penicillin blood levels. Crosson and associates¹⁸ reported that 2 Gm. of caronamide did not have an appreciable effect on the penicillin levels in one of their patients who was receiving 100,000 units of penicillin intramuscularly, whereas the dose was effective in other patients receiving 50,000 units of penicillin. While the age of their patient is not given, the data presented in the foregoing show that 4 Gm. of caronamide is necessary to enhance penicillin levels in persons under 60 years of age who are receiving 100,000 units of penicillin intramuscularly every eight hours and have reasonably good renal function.

Rapoport and co-workers¹⁷ noted significant increases in penicillin blood levels in children with the use of 0.2 Gm. of caronamide per kilogram per day. In adults averaging 60 kilograms in weight, the corresponding dose (namely, 12 Gm. per day) was found adequate for the purpose of increasing the blood levels from the intramuscular dose of penicillin used here only in subjects over 60 years of age. In younger adults twice this amount was necessary to obtain a similar result.

The relative effect of any given dose of caronamide on the blood levels obtained from varying doses of penicillin was not studied.

A comparison of the curves in Fig. 1 shows that the rate of disappearance of penicillin from the blood is significantly slower in the patients over 60 years than in the younger subjects. Since penicillin is excreted chiefly by the tubules, even a major diminution in glomerular filtration could not explain the difference in excretion between the younger and older groups of patients. Presumably, therefore, the reduced rate of disappearance of penicillin from the blood of the older patients is due to a reduction in their functional tubular mass.

Examination of Fig. 1 also shows that the administration of caronamide alters the penicillin blood level curve in young people in a manner qualitatively similar to the alteration apparently caused by age alone. Furthermore, the fact that less caronamide is required to enhance the penicillin levels significantly in the older patients is further evidence of reduced tubular excretory function in the older people.

SUMMARY AND CONCLUSIONS

Caronamide administered orally in doses of 2 Gm. every four hours to patients over 60 years of age markedly enhanced the plasma penicillin levels resulting from the intramuscular administration of 100,000 units of penicillin every eight hours. It was necessary to increase the caronamide dosage to 4 Gm. every four hours in order to produce a similar effect in younger persons. The penicillin blood levels following intramuscular administration of 100,000 units of penicillin every eight hours to patients receiving approximately minimal effective oral doses of caronamide were significantly higher than those obtained by giving 300,000 units of penicillin alone to similar subjects.

The authors are indebted to Dr. William P. Boger, Sharp & Dohme, Inc., Philadelphia, Pa., for the supply of caronamide and for sending us the manuscripts dealing with this drug prior to publication.

ENHANCEMENT OF PLASMA PENICILLIN CONCENTRATIONS BY CARONAMIDE AND SODIUM BENZOATE

ELIAS STRAUSS, M.D., PAUL L. RICHBURG, M.D., PHILLIP Z. SABA, M.D.,
AND J. ERNEST ALEXANDER, M.D.
DALLAS, TEXAS

INTRODUCTION

A CONSIDERABLE number of drugs and vehicles have been introduced into clinical practice in an attempt to improve the practical therapeutics of penicillin by enhancing and prolonging its effective concentration in the blood. Among other agents, benzoic acid and sodium benzoate have been used rather widely to elevate and prolong plasma penicillin concentrations. Despite their use, however, relatively little data are available with regard to their efficacy. Bronfenbrenner and Favour¹ found that blood penicillin concentrations were doubled when benzoic acid was also administered. Bohls and co-workers^{2, a, b} reported measurable blood concentrations of penicillin for twenty-four or more hours following both intramuscular and oral administration of an aluminum-penicillin mixture with benzoic acid or sodium benzoate. These results were not confirmed by Spaulding and associates,³ who found only a moderate enhancement of plasma penicillin concentrations, in some instances for six hours, following the oral administration of several preparations of penicillin with sodium benzoate.

Beyer and associates have introduced a new substance, caronamide, which was found to be effective in enhancing and prolonging penicillin plasma concentrations.⁴ Caronamide (4'-carboxy-phenylmethanesulfonanilide) is a stable, crystalline, colorless compound with little or no odor or taste, only slightly soluble in water, and relatively stable to hydrolysis with acids or alkali. In renal clearance studies in dogs it was demonstrated that caronamide decreased tubular excretion and increased the plasma concentration of penicillin.⁵ When caronamide was given in a dosage of 50 mg. per kilogram the renal clearance of penicillin approximated that of creatinine, indicating an essentially complete suppression of tubular excretion of penicillin. This effect, which was reversible, persisted for about four hours. Further renal clearance studies indicated that caronamide did not influence the Tm of glucose or arginine, or the clearances of urea, sulfonamides, or creatinine.⁶ As would be predicted, however, it decreased the clearance of para-aminohippuric acid. The mechanism of action of caronamide appears to stand in sharp contrast to para-aminohippurate and diodrast. The latter drugs depress penicillin excretion by a mass competition or blockade phenomenon.^{7, 8} Caronamide, in contrast, is believed to be excreted wholly through the glomerular filtrate. Because caronamide depressed the tubular excretion of penicillin but was not itself excreted

This investigation was aided by grants from the U. S. Public Health Service and the Lederle Laboratories Division, American Cyanamid Company, Pearl River, N. Y.

Received for publication, April 24, 1947.

through the tubules. Beyer postulated that this substance exerts a selective inhibitory effect on the enzymatic mechanism of the renal tubules which effects the elimination of penicillin.⁴

Caronamide was found to exhibit a low order of both acute and chronic toxicity in laboratory animals.⁹ When the drug was given to children for periods of one to two weeks, serious toxic reactions were not observed. The oral administration of caronamide and penicillin resulted in an increase in plasma penicillin concentrations of from 1.8- to 14.5-fold over the concentrations obtained during control periods.¹⁰ Similar results with caronamide were also observed in adults who received penicillin intramuscularly and orally.¹¹

These results appeared to be of sufficient interest to warrant the employment of caronamide under clinical conditions. Approximately thirty-five subjects received caronamide by mouth together with penicillin (1) by mouth, (2) by intramuscular injection in aqueous solution, and (3) by intramuscular injection in peanut oil and beeswax. The effect of caronamide on the plasma concentration of streptomycin was also studied in four individuals.

When it became apparent that caronamide did have an effect on the plasma penicillin concentration, the study was extended to include a comparison of the effectiveness of caronamide and sodium benzoate, individually and in combination, in eight additional subjects.

MATERIALS AND METHODS

The subjects used were all young adults and were either healthy physicians, medical students, and nurses or patients convalescent from a variety of illnesses. The twelve subjects who received penicillin in peanut oil and beeswax had primary or secondary syphilis. None of the subjects had clinical or laboratory evidence of renal disease. All ate a general diet and most of them were ambulatory.

Caronamide* was supplied in tablet form and taken by mouth with water. Individual doses varied from 1½ to 3 Gm. at intervals of two to three hours, as indicated subsequently. Sodium benzoate was put up in soft gelatin capsules and taken by mouth with water, in 2 Gm. doses. The sodium salt of amorphous penicillin was used for intramuscular injection. Penicillin in peanut oil and beeswax was supplied as the calcium salt of amorphous penicillin and contained 300,000 units per milliliter. The preparation of penicillin for oral administration was in the form of tablets, each containing 50,000 units of potassium penicillin G with aluminum hydroxide.*

In all of the studies, each subject served as his own control. On the first day of the test penicillin was given alone, at the intervals and in the dosages indicated subsequently. On the following day, the same dosage schedule of penicillin was resumed and, in addition, either caronamide or sodium benzoate, or both, were administered. Oxalated blood samples were obtained at the same hours on each day of the study.

An attempt was made to administer the drugs between meals, allowing an hour between medication and the ingestion of food. Subjects were asked to

*Supplied by Dr. J. W. Crosson, of Sharp & Dohme, Inc., Philadelphia, Pa.

maintain the same diet and fluid intake on each day of the test, but no restrictions were imposed on salt or water intake. Close control of the schedules of meals and medication were not always possible, and it is not known, in some instances, how carefully the instructions were followed.

Plasma penicillin concentrations were determined by a modification of the serial dilution method of Rammelkamp.¹² The medium used was brain-heart infusion broth.* The test organism was a hemolytic streptococcus (strain No. 98†) which was inhibited by 0.008 unit of penicillin per milliliter of broth. The end points of the plasma specimens were determined by the presence or absence of growth of explants on blood agar from the tubes with the highest dilutions of plasma which were clear after twenty-four hours' incubation. Despite the recognized inaccuracies of the method, replicate determinations on the same samples yielded the same results. The method is believed accurate for the detection of concentrations of 0.03 unit or more of penicillin per milliliter of plasma.

Caronamide and sodium benzoate in concentrations of 1 mg. per milliliter of broth did not inhibit the growth of the test organism. These concentrations of the drugs, alone and in combination, did not interfere with the in vitro activity of penicillin, in either broth or diluted plasma. Moreover, the plasma obtained from an individual one and one-half hours after the ingestion of 3.0 Gm. of caronamide did not affect the activity of penicillin in vitro. It was concluded, therefore, that the effects of these agents on plasma penicillin concentrations were not due to interference with the sensitivity of the penicillin assay procedure itself.

RESULTS

Effect of Caronamide.—

Penicillin Administered by Mouth: The effect of caronamide on orally administered penicillin was studied in seventeen tests performed on thirteen subjects. In twelve tests (ten subjects) 100,000 units of penicillin were taken by mouth at two-hour intervals from 8 A.M. to 4 P.M. On the next day, the same dosage of penicillin was resumed and, in addition, the subjects received 2 Gm. of caronamide by mouth every two hours from 6 A.M. to 4 P.M. In six tests blood samples were obtained one hour after each dose of penicillin on both days of the tests; in the other six tests the blood samples were obtained two hours after each dose of penicillin and immediately preceding the next dose. The resulting plasma penicillin concentrations are shown in Tables I and II. There can be little doubt that when these subjects received caronamide, the concentrations of penicillin in the plasma were increased as compared with the control periods. In twenty-five paired tests with blood obtained one hour after each dose of penicillin, the plasma concentrations of penicillin were the same with and without caronamide in three, lower with caronamide only once, and higher with caronamide in twenty-one tests. The increase in penicillin concentration associated with the administration of caronamide was twofold in nine, fourfold in five, and eightfold or more in seven

Caronamide (2 Gm. P.O.) at 6, 8, and 10 A.M., 12 N., and 2 P.M.

Penicillin (100,000 units P.O.) at 8 and 10 A.M., 12 N., and 2 P.M.

(Table I). Similar results were obtained with the twenty-four paired blood samples obtained two hours after each dose of penicillin (Table II). The plasma penicillin concentrations were the same with and without caronamide in five instances, lower with caronamide once, and higher with caronamide in eighteen tests. The increase was twofold in ten, fourfold in four, and eightfold or more in four. Tabulation of the results obtained both one and two hours after the administration of penicillin indicates that the concurrent administration of caronamide was associated with an enhancement of the plasma penicillin concentrations in 80 per cent of the paired blood samples; in 40 per cent this increase was fourfold or greater as compared with the controls. In terms of actual plasma penicillin concentrations, 62 per cent of the blood samples obtained while the subjects were receiving caronamide had a concentration of 0.1 unit or more of penicillin per milliliter of plasma. In contrast,

only 14 per cent of the samples obtained during the control period, on penicillin alone, had concentrations of 0.1 unit or more of penicillin per milliliter of plasma.

Five subjects received 2 Gm. of caronamide and 100,000 units of penicillin by mouth every three hours during the day. Blood samples were obtained three hours after each dose and immediately preceding the next dose. In three of these subjects, on another day, penicillin alone was given and bleedings obtained on the same schedule. Plasma concentrations of penicillin were low in all instances. Only two of nine samples taken while the subjects were receiving penicillin alone contained measurable amounts of penicillin (0.03 unit per milliliter). When the subjects received caronamide in addition, four of twelve samples contained 0.03 unit per milliliter of penicillin. The advantage of caronamide appeared to be negligible. It is evident, therefore, that while caronamide in the dosage used served effectively to elevate the plasma penicillin concentration for a period of two hours after the oral administration of 100,000 units of penicillin, the effect was dissipated within three hours.

Penicillin Administered Intramuscularly: Two subjects received intramuscular injections of 25,000 units of penicillin and two received 50,000 units of penicillin at two-hour intervals from 8 A.M. to 4 P.M. On the following day, the same dosage schedule of penicillin was resumed and, in addition, the subjects received 2 Gm. of caronamide by mouth every two hours, from 6 A.M. to 4 P.M. The plasma penicillin concentrations obtained one hour after each injection of penicillin are shown in Table III.

---, Blood sample not obtained.

In ten paired determinations in subjects on the 25,000 unit dosage schedule, the plasma penicillin concentrations were higher when caronamide was given in eight instances and the same in two instances. Seven of the ten blood specimens obtained when the subjects received caronamide had plasma concentrations of penicillin of 0.2 unit per milliliter or more. When the same subjects received penicillin alone, none of the ten specimens contained more than 0.1 unit of penicillin per milliliter of plasma.

In the subjects who received 50,000 units of penicillin, plasma penicillin concentrations were again higher (in six of eight paired specimens) when caronamide was administered concurrently. In general, the subjects who received caronamide with 25,000 units of penicillin had about the same plasma penicillin concentrations as those who received twice as much penicillin without caronamide.

Caronamide also effectively elevated the penicillin concentrations in the plasma of three other individuals who received 40,000 units of penicillin intramuscularly and 2 Gm. of caronamide by mouth at three-hour intervals during the day (Table VI). Blood samples were obtained one and one-half hours after each dose. Plasma penicillin concentrations were increased twofold or more in ten of twelve paired blood samples.

One of the subjects who had previously been given 50,000 units of penicillin was given two injections of 100,000 units of penicillin intramuscularly at 8 A.M. and 12 N. The following day, he was given the same amount of penicillin at the same hours, and, in addition, took 2 Gm. of caronamide at 6, 8, and 11 A.M. and 2 P.M. Plasma penicillin concentrations obtained one, three, and four hours after each dose of penicillin were identical on each day.*

Caronamide (2 or 3 Gm. P.O.) one hour before and at the time of administration of penicillin.

In eight subjects, plasma penicillin concentrations were determined at intervals following single intramuscular injections of penicillin. On the afternoon of the same day or the next day, the penicillin injections were repeated and, in addition, 2 or 3 Gm. of caronamide were given one hour before the penicillin injection and again at the time of the injection. The results which are recorded in Table IV indicate no significant effects of caronamide on the plasma penicillin concentrations. The discrepancy between these findings and those recorded in the foregoing may be due to the pharmacologic properties of caronamide. It would appear that the substance is either slowly absorbed or else requires a considerable period of time before it exerts its depressant effects on the renal excretory apparatus.

Penicillin Administered in Peanut Oil and Beeswax: The effect of caronamide on plasma penicillin concentrations eighteen and twenty-four hours after

*Subsequent experience with other subjects has indicated that caronamide is effective in elevating plasma penicillin concentrations as much as fourfold, when doses of 200,000 units of penicillin are administered every three hours.

the injection of 600,000 units of penicillin in peanut oil and beeswax was determined in twelve patients with early syphilis.* On the first day of the test, 600,000 units of penicillin (2 ml.) were administered intramuscularly in the buttock at 2 P.M.; at the same time, 1½ Gm. of caronamide were given by mouth and its administration continued thereafter every two hours until noon of the following day. Blood samples were obtained at 8 A.M. (eighteen hours) and at 2 P.M. (twenty-four hours) on the second day. Immediately after the second blood sample was obtained another injection of 600,000 units of penicillin in peanut oil and beeswax was given in the other buttock. No further

Caronamide (1½ Gm. P.O.) every two hours for twenty-four hours.

caronamide was given. Blood samples again were taken eighteen and twenty-four hours after the second injection of penicillin. The results are shown in Table V. In the majority of instances plasma penicillin concentrations were higher when caronamide was also given; however, the results were somewhat erratic and difficult to evaluate. Of twenty-four paired blood samples, the penicillin concentrations were higher when caronamide was given in fifteen, the same with and without caronamide in five, and lower with caronamide than without it in four instances. Less than a measurable amount of penicillin (<0.03 units per milliliter) was present in ten samples obtained in the absence of caronamide and in four samples in the presence of caronamide. Moreover,

*These patients were studied by courtesy of Dr. A. G. Schoeh, Dr. L. J. Alexander, and Dr. T. L. Shields, whose cooperation and assistance are gratefully acknowledged.

six of the twelve patients had plasma penicillin concentrations of 0.1 unit or more per milliliter while receiving caronamide, as compared with only two who obtained this concentration of penicillin in the plasma when not receiving caronamide.

Effect of Caronamide on Plasma Streptomycin Concentrations.—The possible value of caronamide in enhancing and prolonging streptomycin plasma concentrations was investigated in four subjects. Two subjects were given intramuscular injections of 0.5 Gm. of streptomycin, at 8 A.M. and 4 P.M., and caronamide was given by mouth every two hours from 6 A.M. to 10 P.M. (total dose, 18 Gm.). Blood samples were obtained two, six, and eight hours after each injection of streptomycin. On the following day the same schedule was followed except for the omission of caronamide. Within the limits of the method, the plasma concentrations of streptomycin were the same whether or not caronamide was given. Two other subjects received single injections of 0.5 Gm. of streptomycin intramuscularly. Blood samples were obtained at intervals for six hours afterward. On the following day, the streptomycin injections were repeated and 2.0 Gm. of caronamide were given by mouth at two-hour intervals for five doses beginning two hours before the streptomycin injection. In one subject, the concentration of streptomycin in the plasma was from one and one-half to two times higher when the caronamide was administered; in the other subject, however, the streptomycin concentrations for six hours after injection were the same with and without the concurrent administration of caronamide.

Effect of Sodium Benzoate Alone and Together With Caronamide.—

Penicillin Administered Intramuscularly: Three individuals received 40,000 units of penicillin intramuscularly every three hours from 8 A.M. to 5 P.M. on each of three consecutive days. On the first day of the test, 2 Gm. of caronamide were taken by mouth at 6, 8, and 11 A.M., and 2 and 5 P.M. On the third day of the test, 2 Gm. of sodium benzoate were taken by mouth at similar hours. Blood samples were obtained one and one-half hours after each injection of penicillin. The plasma penicillin concentrations are recorded in Table VI.

TABLE VI. EFFECT OF CARONAMIDE AND SODIUM BENZOATE ON PLASMA PENICILLIN CONCENTRATION (PENICILLIN: 40,000 UNITS I.M. EVERY THREE HOURS; BLOOD SAMPLES ONE AND ONE-HALF HOURS AFTER EACH DOSE)

SUBJECT	SEX	DRUG	PLASMA PENICILLIN CONCENTRATION (UNITS/ML.)

		+ Sodium benzoate	0.22	0.45	0.45	0.06
J. D.	F	Penicillin alone	0.22	0.06	0.06	0.06
		+ Caronamide	0.22	0.11	0.22	0.22
		+ Sodium benzoate	0.06	0.11	0.22	0.11

Caronamide and sodium benzoate (2 Gm. P.O.) at 6, 8, and 11 A.M., 2 and 5 P.M.
Penicillin (40,000 units I.M.) at 8 and 11 A.M., and 2 and 5 P.M.

Both caronamide and sodium benzoate effectively increased plasma penicillin concentrations. The two drugs appeared to be equally effective since the penicillin concentrations were the same with caronamide as with sodium benzoate four times, higher with caronamide than with sodium benzoate five times, and lower with caronamide than with sodium benzoate three times.

Penicillin Administered by Mouth: In three subjects who received penicillin by mouth, a comparison was made of the value of caronamide and sodium benzoate individually and together in increasing the penicillin concentration of the plasma. Penicillin, 100,000 units by mouth, was administered every two hours from 8 A.M. to 2 P.M. on each of four consecutive days. On the first day of the test, 2 Gm. of caronamide were also taken by mouth at 6, 8, and 10 A.M., 12 N., and 2 P.M. On the second day, 2 Gm. of sodium benzoate were taken at the same hours in place of the caronamide. On the third day, neither caronamide nor sodium benzoate was administered with the penicillin. On the fourth day both caronamide and sodium benzoate, 2 Gm. of each, were taken at two-hour intervals from 6 A.M. to 2 P.M. Blood samples were secured two hours after each dose of penicillin on each day of the test. The resulting plasma penicillin concentrations are recorded in Table VII (part of the data is also included in Table II).

TABLE VII. EFFECT OF CARONAMIDE AND SODIUM BENZOATE, INDIVIDUALLY AND IN COMBINATION, ON PLASMA PENICILLIN CONCENTRATION
(PENICILLIN: 100,000 UNITS BY MOUTH EVERY TWO HOURS;
BLOOD SAMPLES TWO HOURS AFTER EACH DOSE)

		+ Sodium benzoate	0.06	0.06	0.06	0.03
		+ Combination	0.22	0.06	0.11	0.06

Caronamide and sodium benzoate, each (2 Gm. P.O.) at 6, 8, and 10 A.M., 12 N., and 2 P.M.
Penicillin (100,000 units P.O.) at 8 and 10 A.M., 12 N., and 2 P.M.

In these subjects, caronamide alone was relatively ineffective in raising the penicillin concentration. A twofold or greater increase (as compared with the controls) was recorded in seven of twelve blood samples, but in only one specimen was there a fourfold increase. Sodium benzoate was more effective than caronamide. Three-fourths of the blood samples obtained when sodium benzoate was taken contained more penicillin than the controls; but here, too, in the majority the increase was not greater than twofold. In contrast, the combination of both caronamide and sodium benzoate resulted in a marked enhancement of plasma penicillin concentrations and yielded better results than either drug alone. A fourfold or greater increase in the penicillin con-

centration was obtained in ten of the twelve blood samples, as compared with the controls. Two-thirds of the blood samples obtained on this regimen contained 0.1 unit of penicillin per milliliter of plasma, and none contained less than 0.06 unit.

It was previously demonstrated that measurable amounts of penicillin did not persist in the blood for three hours after the oral administration of 100,000 units of penicillin, taken alone or with caronamide. It was, therefore, of interest to determine the duration of the effect of both caronamide and sodium benzoate. Two subjects took 100,000 units of penicillin and 2 Gm. each of caronamide and sodium benzoate by mouth every three hours during the day. Blood samples were obtained three hours after each dose of penicillin. In five of six blood samples obtained, measurable concentrations of penicillin (0.03 unit or more) were present.

Toxicity of Caronamide and Sodium Benzoate: Approximately fifty adult subjects took caronamide by mouth. The majority received the drug for one day or less; a few took it for as long as three days. The maximum total daily dosage was 18 Gm.; the majority took 10 to 12 Gm. within a twelve-hour period. Gastrointestinal intolerance was the only evidence of toxicity noted. Two subjects complained of nausea and mild diarrhea, the latter persisting for two days. These symptoms began, however, the day after the administration of caronamide and at a time when the subjects were continuing to take penicillin by mouth. The intolerance cannot clearly be ascribed, therefore, to caronamide. Two other subjects complained of nausea and diarrhea for one day coincident with the ingestion of penicillin, caronamide, and sodium benzoate. Again it is impossible to decide which of the three drugs or whether the combination of them was responsible for the gastrointestinal disturbance. Since this reaction occurred in two of the five subjects who received all three drugs at the time, it is likely that a considerable percentage of individuals placed on this regimen will be unable to tolerate it.

DISCUSSION

The observation that a combination of caronamide and sodium benzoate resulted in higher penicillin blood concentrations than were attained by the use of each drug alone is of particular interest with regard to the mode of action of these agents. Two possible explanations are suggested: (1) that the dose of each drug was inadequate for maximal effect and (2) that caronamide and sodium benzoate act by different mechanisms. Since a rather fixed dosage schedule of caronamide was used in these studies, the validity of the first explanation cannot be established. It may be noted, however, that the total dose of caronamide usually given within four or six hours was close to that required to produce complete suppression of tubular excretion of penicillin in dogs.⁵ The assumption has been made that benzoic acid and sodium benzoate act in a manner similar to diodrast⁷ and p-aminohippurate,⁸ competing with penicillin for a common renal tubular excretory mechanism. The evidence of Beyer bearing on the mode of action of caronamide has been referred to previously.⁴ Recently, evidence has been presented that sodium benzoate has an antipeni-

icillinase effect.¹³ It has been suggested that this property, rather than a blocking action on the renal tubules, is responsible for the observed action of sodium benzoate. If such were the case, the apparent synergistic effect of caronamide and sodium benzoate could be explained as the summation of two different mechanisms, each of which helps to maintain the penicillin concentration in the blood. In vitro we have noted that caronamide also exhibits an antipenicillinase effect but do not believe that this action offers an explanation for its behavior in the body, especially since normal pooled plasma also exhibits an antipenicillinase effect which is greater than that of caronamide.

The present studies appear to be sufficiently detailed to indicate the probable value of caronamide as an adjunct to penicillin therapy. It is clear that caronamide is effective in elevating the penicillin concentration in the blood; however, for this purpose, its effectiveness appears to be no greater than that exhibited by sodium benzoate. The choice of either drug would seem therefore to depend in part on the respective toxicity of the two agents. Sodium benzoate is regarded as an innocuous substance,¹⁴ its principal disadvantage being its rather frequent nauseant action. Enough experience has not as yet accumulated to assess the incidence of toxic reactions or idiosyncrasies to caronamide. Until such experience is gained under controlled conditions of observation, its routine use in preference to sodium benzoate is not recommended.

When penicillin was given intramuscularly in aqueous solution, the concurrent administration of caronamide or sodium benzoate resulted in a twofold or greater increase in the concentration of penicillin in the plasma in most instances. However, no studies were made as to the total duration of this effect of caronamide. Essentially the same blood concentrations of penicillin were attained with the injection of 25,000 units of penicillin plus caronamide as resulted from the injection of 50,000 units of penicillin without an adjuvant. Such blood concentrations of penicillin are probably entirely adequate for the control of infections due to organisms ordinarily responsive to penicillin therapy, except for those due to unusually resistant strains. If toxicity and intolerance do not prove to be limiting factors in the use of caronamide, this drug plus 25,000 units of penicillin, intramuscularly, every two hours, will probably result in the maintenance of adequate blood penicillin concentrations. Such a regimen, however, while saving of penicillin, does not obviate the need for repeated injections, which is one of the chief disadvantages of penicillin treatment. From a practical viewpoint, therefore, the chief interest in such substances as caronamide and sodium benzoate lies in their possible value in enhancing the effectiveness of penicillin when given by mouth or in single daily injections in peanut oil and beeswax.

Although it is impossible to define an adequate level of penicillin, experience with in vitro tests indicates that penicillin concentrations of 0.03 to 0.06 unit per milliliter are generally adequate for control of infection with the majority of strains of pneumococcus, hemolytic streptococcus of group A, gonococcus, and *Streptococcus viridans*. From two to eight times as much penicillin may be needed for the control of infections due to some strains of these organisms as well as to many strains of staphylococcus and meningococcus.¹⁵ In

the present study, when 100,000 units of penicillin were taken orally every two hours, adequate plasma penicillin concentrations were not achieved in a large proportion of the blood samples. Two-thirds of the blood specimens obtained one hour after this oral dose of penicillin, and one-half of the specimens obtained two hours after this dose, contained 0.03 unit or less per milliliter.

Caronamide was of definite value in enhancing the penicillin concentration in the plasma when penicillin was given by mouth. In 80 per cent of the blood samples obtained one and two hours after the ingestion of 100,000 units of penicillin, the administration of caronamide was associated with a twofold or greater increase in the plasma penicillin concentration; in 40 per cent the increase was fourfold or greater over the corresponding control samples. When the subjects took caronamide, 70 per cent of the blood specimens contained 0.1 unit or more per milliliter one hour after the dose of penicillin, and 54 per cent of the samples still contained 0.1 unit or more per milliliter two hours after the dose of penicillin. Unfortunately, caronamide did not maintain adequate penicillin concentrations for three hours. The effect of sodium benzoate was essentially the same as that of caronamide for two hours after the oral dose of penicillin. The duration of effect of this drug was not measured beyond two hours, but the data strongly suggested that sodium benzoate likewise does not maintain effective plasma penicillin concentrations for three hours after a dose of 100,000 units of penicillin orally. The combination of sodium benzoate and caronamide together with 100,000 units of penicillin orally, every three hours, resulted in optimal plasma concentrations for two hours and adequate concentrations of penicillin for three hours. Although this regimen appears to yield good results, it seems likely that a considerable number of patients will be unable to tolerate it.

While the foregoing data suggest the value of caronamide or sodium benzoate as adjuvants for the successful use of orally administered penicillin, they omit consideration of a serious limitation; namely, the differences in response which individual subjects exhibited. When oral penicillin was given alone, variations in the plasma concentrations attained were evident not only in different subjects, but also in the same subjects from hour to hour. The time of ingestion of meals and the fluid intake have an important influence on blood concentrations of penicillin,^{1, 16} and such influences were undoubtedly responsible for some of the variations observed. When caronamide was taken, however, the individual variations in plasma penicillin concentrations were greatly accentuated. For example, Subject P. R. (Tables I, II, and VII) consistently exhibited a poor response to caronamide and to sodium benzoate; Subject N. P. (Table I), on the contrary, had an unusually good effect from the administration of caronamide. Such unpredictable individual variations, while recognized in the pharmacology of all drugs, have been particularly noted with the oral administration of penicillin.³ They render uncertain any attempt to define minimal effective dosage schedules for penicillin, which can be used routinely without the necessity of measuring the blood concentrations.

In keeping with the findings of others,¹⁷ the results in the present study indicate that only a minority of patients maintain an effective concentration

of penicillin in the blood twenty-four hours after the intramuscular injection of 600,000 units of penicillin in peanut oil and beeswax. Less than 0.03 unit of penicillin per milliliter of plasma was present at twenty-four hours in seven of twelve patients, and only two had concentrations of 0.1 unit or more. It is, therefore, of interest that when caronamide was administered throughout the twenty-four hours following the injection of penicillin in wax and oil, only three of twelve had plasma penicillin concentrations of less than 0.03 unit per milliliter, and six had 0.1 unit or more per milliliter of plasma. The inconsistencies in the results, however, are such that a definite opinion as to the value of caronamide cannot be expressed. Individual variations are undoubtedly of importance when penicillin is administered by this route as well as by mouth. and, in addition, such factors peculiar to this route of administration as the accuracy of measurement of the dosage, variations in the site of deposition of the penicillin in the tissues, and amount of muscular activity, influence the resulting plasma penicillin concentrations.

The foregoing discussion implies a field of usefulness for caronamide and sodium benzoate which practical considerations may negate. Despite their effect, it is believed that these drugs will prove to be of only limited value when penicillin is given by intermittent intramuscular injection. The saving in the cost of penicillin may be more than offset by the inconvenience and potential toxicity of additional medications.* A similar conclusion probably also will soon apply to penicillin in peanut oil and beeswax. Larger doses in more convenient preparations will obviate the need for adjuvants such as these.

In the field of oral penicillin therapy these substances may have greater usefulness. In terms of the plasma penicillin concentrations attained, oral therapy is not only inefficient and costly, but also unreliable. The addition of caronamide or sodium benzoate, while not permitting any reduction in the dosage of oral penicillin, at least appears to assure more satisfactory blood concentrations than can be obtained without them.

SUMMARY AND CONCLUSIONS

1. The effectiveness of caronamide (4'-carboxy-phenylmethanesulfonanilide) in enhancing the plasma penicillin concentration was studied in thirty-five adult subjects. This effect was compared with that of sodium benzoate.

2. The only toxic effects of caronamide encountered were nausea and mild diarrhea in a few individuals.

3. The administration of 100,000 units of penicillin by mouth resulted in low plasma concentrations one and two hours after each dose. The concurrent administration of caronamide resulted in a twofold or greater increase in plasma penicillin concentrations in 80 per cent of the blood samples, and a fourfold or greater increase in 40 per cent of the samples. This enhancement of the plasma penicillin concentration by caronamide was maintained for two hours but not for three hours after each dose of penicillin.

*Experience acquired since the completion of this manuscript indicates that in situations in which more than a million units of penicillin per day are required, the concurrent administration of caronamide may be of considerable value. Increases of twofold or greater in plasma penicillin levels may be obtained, and result in considerable saving in the amounts of penicillin required.

4. In subjects who received 25,000 and 50,000 units of penicillin intramuscularly, the concurrent oral administration of caronamide likewise resulted in two- to eightfold increases in plasma penicillin concentrations in most instances. When penicillin was injected in peanut oil and beeswax the effects of caronamide were variable, but in the majority of instances plasma penicillin concentrations were increased.

5. Caronamide had no effect on the plasma concentration of streptomycin when the latter substance was administered in multiple intramuscular injections.

6. In general, sodium benzoate was as effective as caronamide in increasing plasma penicillin concentrations when penicillin was given by mouth or by intramuscular injection. The ingestion of both sodium benzoate and caronamide by subjects receiving penicillin by mouth resulted in a greater enhancement of plasma penicillin concentrations than was effected by either of these agents alone.

Technical assistance was given in these studies by Anna Maxell.

A WATER-SOLUBLE PREPARATION FOR PROLONGING EFFECTIVE PENICILLIN LEVELS IN BODY FLUIDS

LEO LOEWE, M.D., HAROLD B. FIBER, M.D., ERNA ALTRE-WERNER, PH.D.,
AND MARY KOZAK SHORE, A.B.
BROOKLYN, N. Y.

THE exigencies of routine clinical practice frequently call for the use of a single daily dose injectible preparation of penicillin that can be relied upon to obtain and maintain effective therapeutic levels of the antibiotic in body fluids. The preparation, ideally, must be stable, water soluble, nontoxic, and nonirritant, and it must be capable of easy and safe administration.

To meet these basic criteria, the following formula* has been developed and employed successfully:

Crystalline sodium salt of penicillin G (300,000 Oxford units)	180.0 mg.
Ephedrine sulfate	25.0 mg.
Epinephrine dihydrochloride	1.0 mg.
Eucupine dihydrochloride	1.0 mg.
Gelatin-dextrose mixture (dried weight)	800.0 to 1,200.0 mg.

When sterilized, dehydrated, and bottled, the preparation appears as a homogeneous powder. On the addition of 2 ml. of distilled water, the powder dissolves readily at room temperature and with great facility if the container is agitated or gently heated by immersion in hot tap water. The resultant amber-colored, water-clear solution may then be drawn up into a 5 or 10 ml. syringe through an 18- or 19-gauge needle and injected without undue haste, subcutaneously or intramuscularly, using a 20-gauge needle. A delay in injection of more than thirty minutes at room temperature may solidify the gel which can then again be fluidified by gentle heat as indicated.

RATIONALE

The vehicle, as described, is composed of penicillin, vasoconstrictors, a local anesthetic, and the gelatin-dextrose mixture. The final pH of the dehydrated preparation, as bottled, is 6.0.

Crystalline sodium penicillin G, 300,000 Oxford units, is the conventional dose for repository injection. It is noteworthy that special penicillins, such as the calcium salt, are not essential for this preparation. If it is desirable to augment the standard dosage, it can be done by merely incorporating additional penicillin in the 2 ml. sterile distilled water which is used to reconstitute the preparation.

From the Department of Medicine and Department of Laboratories, Jewish Hospital of Brooklyn.

Aided by grants from the John L. Smith Fund for Medical Research and William R. Warner & Co., New York, N. Y.

Received for publication, April 7, 1947.

*The penicillin and gelatin-dextrose preparations were supplied by Chas. Pfizer & Co., Inc., Brooklyn, N. Y. We are indebted to Dr. Richard Pasternack, of that organization, for his interest and cooperation.

The vasoconstrictors are included for additive prolonging effects. Following the injection, because of the vasoconstrictor drugs, the patient may occasionally complain of transitory palpitation and nervousness. No objective vasoconstrictor effects have been observed in any of the subjects.

The eucupine dihydrochloride serves as a local anesthetic. The hydrogen-ion concentration of 6.0 is optimal. With this pH the penicillin remains stable at room temperature for long periods of time. Furthermore, there is no deterioration of the vasoconstrictor drugs nor is there precipitation of the eucupine dihydrochloride.

In the course of our studies with heparin, the Pitkin menstruum was adopted as the vehicle in order to accomplish a slower and more equable absorption of the drug and to supplant the cumbersome technique of intravenous administration.^{1, 2} The Pitkin menstruum was devised for regulating and retarding the rate of release of water-soluble drugs injected subcutaneously or intramuscularly. The clinical department of heparin in the Pitkin menstruum has been reported on several occasions.³⁻⁵

The possibility of utilizing the Pitkin menstruum for penicillin was explored with only partially successful results because both the water content and the low pH induced by the acetic acid in the menstruum were deleterious to penicillin.

These shortcomings were overcome by (1) the selection of gelatins which are more compatible with penicillin and more physiologically acceptable by body tissues, (2) elimination of acetic acid, (3) adjustment of pH, and (4) dehydration of the preparation.

The selection of a satisfactory gelatin* is predicated on several factors. While gelatins are nonallergenic and therefore may be employed in preparing vehicles for intramuscular injections, they differ considerably in their chemical and physical properties, depending upon the source material and method of extraction.

The gelatin of choice must have a suitable molecular weight and jelly strength. To be of practical value this gelatin must lend itself readily to dehydration and reconstitution in aqueous solution at room temperature.

TECHNIC OF ADMINISTRATION

The steps in the administration of the preparation have been previously indicated but may be summarized as follows:

1. Warm the bottle by immersion in hot water and/or by agitation.
2. Expose the rubber diaphragm and sterilize with alcohol; inject 2 ml. of sterile distilled water.
3. Reimmerse the bottle in warm water in a basin or under the tap.
4. With an 18- or 19-gauge needle withdraw the solution into a 5 or 10 ml. sterile syringe.
5. Substitute a 20-gauge needle and inject the gel subcutaneously or intramuscularly, first withdrawing the piston slightly to make sure that a vein has not inadvertently been entered.

*We wish to express our appreciation to Dr. Thomas B. Downey, of the Kind-Knox Gelatin Co., Camden, N. J., for his interest and cooperation in this phase of our problem.

RESULTS

The clinical department of the various dehydrated penicillin and gelatin-dextrose preparations has been observed in over 300 subjects. The series included normal controls and ambulatory and bed patients with and without infections. These clinical observations were for the purpose of establishing the composition of the optimum preparation, having in mind its anti-infective properties, its effectiveness in prolonging penicillin levels in body fluids, the absence of toxicity, freedom from local reactions, and ease of administration. Stability studies on the preparation were also carried out with bottles that were stored at room temperature for more than a year.

Fig. 1.

Analysis of data (Table I) and a composite graph (Fig. 1) of blood levels* of twenty-four consecutive patients disclose measurable amounts of penicillin up to twenty-four hours following a single dose of 300,000 Oxford units in the gelatin-dextrose preparation. The pattern of blood levels in this group of twenty-four patients is characteristic for all subjects receiving the optimum preparation. The average blood penicillin levels are at peak during the initial eight to thirteen hours (0.08 to 1.91 Oxford units per milliliter) and then taper off to a level (0.015 Oxford units per milliliter) which is still bacteriostatic for many of the ordinary penicillin-inhibitable infecting organisms. These include most strains of gonococci, pneumococci, hemolytic streptococci, and staphylococci. In no instance has the preparation of choice been toxic or productive of local reactions.

*The penicillin assay method used was that described by Rosenblatt, Altire-Werber, Kashdan and Loewe,⁶ which employs *Streptococcus pyogenes* C203 as test organism. In a comparative study this system was found by Dolkart, Dey, and Schwemlein⁷ to yield generally and, at times, appreciably lower values than the Food and Drug Administration assay procedure described by Randall, Price, and Welch,⁸ which uses *Bacillus subtilis* NRRL B-558 as the test organism.

RESULTS

The clinical deportment of the various dehydrated penicillin and gelatin-dextrose preparations has been observed in over 300 subjects. The series included normal controls and ambulatory and bed patients with and without infections. These clinical observations were for the purpose of establishing the composition of the optimum preparation, having in mind its anti-infective properties, its effectiveness in prolonging penicillin levels in body fluids, the absence of toxicity, freedom from local reactions, and ease of administration. Stability studies on the preparation were also carried out with bottles that were stored at room temperature for more than a year.

TABLE I. ANALYSIS OF BLOOD PENICILLIN LEVELS IN A SERIES OF TWENTY-FOUR PATIENTS INJECTED (SUBCUTANEOUSLY OR INTRAMUSCULARLY) WITH 300,000 UNITS OF PENICILLIN IN THE GELATIN-DEXTROSE PREPARATION

NUMBER OF PATIENTS TESTED	1 HR.	4 HR.	7 HR.	10 HR.	13 HR.	16 HR.	19 HR.	22 HR.	24 HR.
	24	24	24	24	24	23	22	16	6
Number of patients with a level of 0.03 units per milliliter or more	24	24	24	24	23	15	4	0	0
Per cent	100	100	100	100	95	65	18	0	0
Average level (from all determinations) units per milliliter	1.91	1.62	0.89	0.35	0.09	0.03	0.03	0	0
Number of patients with a level of 0.015 units per milliliter or more	24	24	24	24	24	23	22	16	3
Per cent	100	100	100	100	100	100	100	100	500.0
Average level (from all determinations) units per milliliter	1.91	1.62	0.89	0.35	0.08	0.03	0.02	0.016	50

The therapeutic application of this preparation has been studied in various diseases such as gonorrhea, pneumococcus pneumonia, streptococcus sore throat, and furunculosis. The results of these studies will be the subject of subsequent reports.

DISCUSSIONS

Ever since penicillin became available for clinical use, attempts have been made to devise methods for administering this agent which would overcome its inordinately rapid loss through the kidneys. Although this problem has engaged the attention of numerous investigators, recourse, for the most part, must still be made to conventional, fractional intramuscular injections or continuous venoclysis.

Even with two-hour intermittent, intramuscular injections, there is a fraction of the treatment period wherein there is little or no assayable penicillin in the blood. About 60 per cent of the parenterally administered penicillin is excreted in the urine, mostly within one hour after intramuscular injection of the aqueous solution. As a result, in some infections treatment failure is almost inevitable. This is especially true of infections caused by the more resistant types of organisms. Furthermore, in long-continued infections repeated intramuscular injections become irksome and distressing. Continuous intravenous administration is resorted to in these circumstances, usually with gratifying results. The continuous venoclysis route is still the method of choice, however, where uninterrupted massive dosages are required over extended periods of time, as in the treatment of subacute bacterial endocarditis.^{9, 10} It may even be necessary to incorporate in the treatment program some potentiating agent such as sodium para-aminohippurate in order to achieve requisite blood penicillin assays.¹⁰⁻¹³

Penicillin has been emulsified in beeswax and peanut oil¹⁴ and in oil and water mixtures¹⁵ as a means of retarding absorption and prolonging the action

of penicillin and thus obviating frequent repeated intramuscular injections necessary with aqueous solutions. While the penicillin assays in body fluids of patients so treated reveal adequate levels for acute infections, the continued use of these foreign insoluble vehicles has certain disadvantages. Local reactions are common,¹⁶ and foreign body tissue responses have been reported following these repositories.¹⁷ Additional drawbacks of the oil and beeswax preparations are lack of stability at room temperature and technical difficulties of administration. For these reasons a water-soluble, wholly absorbable, stable, nontoxic vehicle for penicillin is preferable.

SUMMARY AND CONCLUSIONS

A new penicillin preparation for prolonging effective levels in body fluids has been described. It is water-soluble, nontoxic, free of local reactions, and easy to administer. It maintains measurable levels in the blood for periods up to twenty-four hours or longer and has retained its stability at room temperature for more than a year.

USE OF MODIFIED DUBOS AND DAVIS MEDIUM FOR DEMONSTRATION OF ANTIBIOTIC ACTIVITY OF SUBTILIN AGAINST MYCOBACTERIUM TUBERCULOSIS

SAM C. WONG,* ALVIN S. HAMBLEY, JR., AND HAMILTON H. ANDERSON
SAN FRANCISCO, CALIF.

ATTEMPTS to demonstrate the antibiotic activity of subtilin in vitro against *Mycobacterium tuberculosis* by means of the classical Long's synthetic medium have yielded inconsistent results.¹ With any antibiotic, such as subtilin, which has been shown to lose 68 per cent of its activity when held at 37° C., pH 7.3, for six days,² a single, initial application has proved to be inadequate.³ It is obvious that the results obtained at the end of three weeks' exposure (the usual growth period) do not represent initial activity. In addition, the classical method, which consists of floating the inoculum, does not permit intimate contact between the antibiotic and all mycobacteria present in the culture. In fact, only those organisms present in the base and periphery of the inoculum seem to be affected.

A recently developed liquid medium which appears to circumvent these difficulties is that of Dubos and Davis,⁴ who made use of a synthetic wetting agent under the trade name of "Tween 80" to facilitate submerged growth, and a purified albumin (Cohn's Fraction V) to increase the growth rate of mycobacteria. In the present communication we wish to report our experience with the use of this medium to demonstrate the antibiotic activity of subtilin against a virulent strain of *Myco. tuberculosis*.

MATERIALS AND METHODS

Myco. tuberculosis† was the organism employed. Two lots of subtilin, one of which was more toxic for mice than the second, were used. The composition of the slightly modified Dubos and Davis medium is given in Table I. The diluted "Tween 80" solution was autoclaved in the same manner as the medium, while the bovine albumin‡ was sterilized by Seitz filtration. All reagents were chemically pure and the pH of the medium was adjusted to 7.2. It was autoclaved at 15 pounds of pressure for fifteen minutes. The medium was incubated for sterility at 37° C. for twenty-four hours before use. All pH determinations were made with the Beckman pH meter. To demonstrate antibiotic activity the scheme of mixing the subtilin solution and the medium, shown in Table II, was adopted. The subtilin solutions were measured by means of

*Died on the nineteenth day of infection.

1:20,000 dilution or lower of subtilin was definitely bactericidal, while dilutions between 1:40,000 and 1:200,000 of the antibiotic appeared to be bacteriostatic rather than bactericidal. This was substantiated by the finding that five of eight animals inoculated with cultures containing these dilutions revealed various stages of tuberculous infections when animals were sacrificed four weeks after initial infection. In the third place, infections among the experimental animals (Animals 3 to 14) on the whole were less severe than in the controls. This would further indicate that the number of organisms originally present was small since microscopic examinations did not reveal their presence.

A comparison was made between the tuberculin skin test and the macroscopic and the histologic findings in guinea pigs infected with tuberculosis. It was found that histologic studies gave the highest number of positives. Since only one dose of tuberculin was used it is conceivable that animals with early, mild infections may not develop allergy to a degree detectable by 0.01 mg. of P. P. D. In general there is close agreement among the three tests.

COMMENT

The use of modified Dubos and Davis medium has permitted the rapid evaluation of an antibiotic, subtilin, against a virulent strain of *Myco. tuberculosis*, the result of which has, heretofore, been inconclusive. This was effected by incorporating a synthetic wetting agent, "Tween 80," and by the addition of a purified albumin fraction to a simple synthetic medium. The former made possible submerged growth while the latter increased the growth rate of the acid-fast bacilli, all of which favors subtilin standardization.

Although subtilin regularly inhibited the growth of our strain of *Mycobacterium* in concentration of 1:400,000, subsequent animal inoculation revealed

that its bactericidal property in vitro was low. It required a concentration of 1:20,000 to sterilize the organisms employed in these tests. It may be inferred, therefore, that the chief mode of action of this antibiotic in vivo is bacteriostatic since the concentration of this amount in the blood stream or tissues can hardly be achieved. Unpublished data from this laboratory indicate that subtilin is precipitated in the presence of sodium chloride. Concentrations of subtilin (University of California Lots 8 and 10) greater than 0.1 mg. per cent appear to be precipitated in the blood. Nevertheless, the marked bacteriostatic effect shown here in conjunction with the low toxicity of subtilin are favorable indications for therapeutic trials. A less toxic salt-soluble fraction of subtilin is now available for such trials.⁷

SUMMARY

The modified Dubos and Davis medium is suitable for demonstrating the antibiotic activity of subtilin against a virulent human strain of *Myco. tuberculosis*. Under the conditions of the test a 1:400,000 dilution of subtilin regularly inhibited the growth of these organisms, while dilutions of 1:20,000 or lower were required to achieve bactericidal effect.

FURTHER OBSERVATIONS ON THE CULTIVATION OF TUBERCLE BACILLI FROM PATHOLOGIC MATERIAL IN DUBOS MEDIA

GEORGE E. FOLEY
BOSTON, MASS.

INTRODUCTION

THE bacteriologic diagnosis of tuberculosis still is dependent upon the demonstration of the tubercle bacillus by direct microscopic examination, by animal inoculation, by culture, or by various combinations of these methods. Although the guinea pig remains the method of choice, especially with small specimens or specimens of material which are not easily obtainable, the decreasing use of animal injection has placed more and more emphasis on cultures for the diagnosis of those cases which are negative by direct microscopic examination. In the past years several generally satisfactory methods for the cultivation of *Mycobacteria* have been developed, such as Dorset's,¹ Petragrani's,² Löwenstein's,³ and Schwabacher's⁴ variations of coagulated egg media. Most of these, if properly prepared and used with reasonable care, yield a high percentage of positive results. Fundamentally, however, there are two objections which might be made to such media: (1) difficulty in preparation and (2) the time required to obtain growth of tubercle bacilli from pathologic material, often a matter of six or eight weeks.

Dubos⁵ recently described a medium which not only supported the growth of minimal inocula of stock strains of tubercle bacilli, but also permitted the rapid growth of cultures planted with such inocula. Foley⁶ in a recent study found that such media could be used for the isolation of tubercle bacilli from pathologic material. The purpose of the present study is to report further experience with these media in the bacteriologic diagnosis of tuberculosis.

METHODS

In the previous study⁶ several variations of the basic medium as described by Dubos⁵ were employed. Since there appeared to be little difference in the results obtained in these various media, further investigation has been limited to the use of one formula, that most recently described by Dubos⁷ (Table I).

The mineral base can be prepared as a stock solution and then stored at room temperature with the addition of a few drops of chloroform, the various solutions (and agar if desired) being added just prior to use. Serum albumin must be inactivated before use in media containing "Tween" since it may contain sufficient lipase to split "Tween" into free fatty acids which inhibit the growth of the tubercle bacillus. Dubos⁸ recently suggested the addition of sodium fluoride to the medium to inactivate the serum albumin lipase. Preliminary experiments in this laboratory with the H37RV strain indicate that as little as 0.005 per cent sodium fluoride is sufficient to prevent lipase activity and yet not interfere with the growth of the tubercle bacillus.

From the Department of Pathology and Bacteriology, Massachusetts General Hospital.
Presented at a Session of the Laboratory Section of the American Public Health Association at the Seventy-Fourth Annual Meeting in Cleveland, Ohio, Nov. 13, 1946.
Received for publication, April 10, 1947.

TABLE I. CULTIVATION OF TUBERCLE BACILLI FROM PATHOLOGIC MATERIAL:
PREPARATION OF MEDIA

Potassium phosphate (Dihydrogen)	1.00 Gm.
Sodium phosphate (Disodium)	6.25 Gm.
Sodium citrate	1.50 Gm.
Magnesium sulfate	0.60 Gm.
"Tween," 80*	5.00 ml. of 10% aqueous solution
Casein hydrolysate	20.00 ml. of 10% neutral solution
Distilled water ad.	1,000.00 ml.

Adjust to pH 7.0-7.2 with normal sodium hydroxide
 Dispense in 5 ml. volumes in properly prepared tubes
 Autoclave at 15 pounds for fifteen minutes
 To each 5 ml. tube of sterile media, add aseptically:
 0.400 ml. of 5 per cent serum albumin in 2 per cent saline†
 0.005 ml. of 10 per cent vegex,‡ autoclaved aqueous solution
 0.050 ml. of 10 per cent glucose, filtered aqueous solution

*A polyoxyethylene derivative of sorbitan monolaurate, product of Atlas Powder Company, Wilmington, Del. "Tween" must be kept in refrigerator and made up fresh each time medium is prepared. Stored in the mineral base it rapidly splits into products inhibitory to the growth of the tubercle bacillus.

†Bovine fraction V, Armour Laboratories, Chicago, Ill. Desiccated albumin must be kept frozen. Solution prepared fresh in 2 per cent saline for each lot of media, filtered through a Seitz or porcelain filter, and inactivated at 56° C. for thirty minutes.

‡Product of Vegex Corporation, New York, N. Y.

Mineral base may be stored at room temperature with a few drops of chloroform.

"Tween," albumin, glucose, and vegex must be added just prior to use.

All minerals C.P., not recrystallized.

The fluid medium was dispensed in 5 ml. amounts in 7 by 1 Pyrex glass test tubes which previously had been chemically cleaned, rinsed with distilled water, stoppered with cotton, and autoclaved at 15 pounds of pressure for fifteen minutes instead of the usual sterilization by dry heat. The preparation of glassware is most important, since residual soaps, oils rendered from cotton plugs by dry heat, fats, etc., may inhibit the growth of the tubercle bacillus.

Dubos⁵ also has described a solid medium prepared by the addition of 1.5 per cent agar-agar and 0.001 per cent ferric ammonium citrate to the mineral solution with "Tween" (Table I). The mineral base, "Tween," and agar-agar are autoclaved; vegex, glucose, and serum albumin are added aseptically. The agar is dispensed in Petri dishes with moist filter paper attached inside the cover. After inoculation the dish is sealed with adhesive tape to prevent the loss of moisture by excessive evaporation.

For cultural examination, 5 to 20 ml. volumes of the specimens were digested for periods varying from one-half to two hours at room temperature with an equivalent volume of 3 per cent hydrochloric acid, then neutralized to approximately pH 7.0 with 2 per cent sodium hydroxide. The digest was centrifuged and the sediment concentrated in one-tenth to one-twentieth the original volume in sterile physiologic saline. The shorter periods of digestion are desirable since prolonged treatment with acid or alkali undoubtedly kills some of the tubercle bacilli in the sample. Catheterized or bladder urines and gastric aspirations usually can be freed of commensural bacteria by digestion for one-half hour or less, while material such as sputum usually requires longer periods. Media were inoculated with 0.1 to 0.5 ml. of digest and incubated at 37° C. for twenty-one days. Acid-fast smears were examined as soon as visible growth appeared; in any case, on the seventh, fourteenth, and twenty-first days of incubation. The final smear on the twenty-first day was made on the centrifuged sediment of the broth cultures.

Since the previous report,⁶ 197 specimens have been examined for tubercle bacilli by these methods as well as by guinea pig inoculation. Of these, twenty-eight were positive either by culture or guinea pig, or both. The results obtained with these positive specimens are summarized in Table II.

TABLE II. CULTIVATION OF TUBERCLE BACILLI FROM PATHOLOGIC MATERIAL: COMPARISON OF GUINEA PIG INOCULATION WITH CULTIVATION IN DUROS' MEDIA

*Patient with positive culture and negative guinea pig not available for further study.

†One of two guinea pigs positive on each of two specimens which were negative by culture.

RESULTS

As is shown in Table II, twenty-three (82 per cent) of the twenty-eight specimens which contained tubercle bacilli were positive by culture as well as by guinea pig. One additional specimen, a gastric aspiration which was positive by culture, did not produce tuberculosis in guinea pigs. The incubation periods of these positive specimens ranged from five to twenty-one days, with a mean of 10.6 days, remarkably little time for the bacteriologic diagnosis of tuberculosis. The remaining specimens, two sputa and two spinal fluids, were positive by guinea pig only, tubercle bacilli not being found in culture.

The results obtained with this small series of specimens are combined with those previously reported⁶ in Table III. Of the fifty-seven specimens which contained tubercle bacilli, fifty (87.7 per cent) were positive by culture, a figure which is not significantly different from the fifty-four (94.6 per cent) specimens which were positive in guinea pigs. The incubation periods for the positive cultures in this larger series ranged from five to twenty-seven days, with a mean of 10.6 days. Forty-four (88 per cent) of the positive results

*Patient with negative guinea pig and positive culture not available for further study.

†One guinea pig positive on case with negative culture.

‡Two sputa negative in guinea pigs and positive by culture were from known cases of tuberculosis.

were obtained with incubation periods of fourteen days or less, a sharp contrast to the eight to twelve weeks usually required for diagnosis by guinea pig inoculation.

As yet, too few positive specimens have been studied on the solid medium to permit analysis. The few strains isolated as well as the stock cultures of tubercle bacilli grew as small, smooth, soft, colorless, semitransparent colonies after seven to ten days of incubation. Colony morphology was not unlike that of the streptococcus, markedly different from the hard, granular, opaque growth usually observed in coagulated egg media. Four spinal fluids which failed to grow in broth yielded positive results within ten days when cultivated on the agar medium.

DISCUSSION

The specimens (Table IV) with which divergent cultural and guinea pig results were obtained are of particular interest. A positive cultural result with those specimens which were negative by guinea pig suggests either of two explanations: such results merely represent differences in the number of tubercle bacilli in the inocula used for culture and guinea pig or these strains were avirulent. In the case of the two sputa, the former seems the most likely since both specimens were obtained from patients known to have tuberculosis. In the case of the gastric aspiration, repeat specimens for further study were unobtainable and it could not be established whether the patient did or did not have tuberculosis. The microorganism isolated had the cultural and growth characteristics of tubercle bacilli but was avirulent for guinea pigs.

TABLE IV. CULTIVATION OF TUBERCLE BACILLI FROM PATHOLOGIC MATERIAL: DISCREPANT RESULTS BETWEEN GUINEA PIG INOCULATION AND CULTIVATION IN DUBOS' MEDIA

MATERIAL	TOTAL NUMBER OF SPECIMENS	NUMBER OF SPECIMENS		
		POSITIVE G.P. POSITIVE CULTURE	POSITIVE G.P. NEGATIVE CULTURE	NEGATIVE G.P. POSITIVE CULTURE
Gastric aspiration	8	7	0	1
Urine	14	13	1	0
Sputum	16	11	3	2
Spinal fluid	7	4	3	0

A positive guinea pig and a negative culture on the same specimen also is amenable to either of two explanations. If the material contained but a few tubercle bacilli, it is conceivable that acid digestion might reduce the number of viable cells below the minimum necessary for growth in artificial media. The alternate explanation is the probability that certain strains fail to grow in these media. Dubos⁵ feels that the medium does not yet provide the optimal factors essential for the growth of all strains of tubercle bacilli. That there are differences between various strains is well illustrated by the four spinal fluids which were negative in fluid media but yielded prompt positive results when cultured on Dubos' agar.

Saprophytic Mycobacteria as yet cannot be sufficiently differentiated to permit the exclusive use of these media for the specific diagnosis of tuber-

culosis on certain kinds of material; namely, urine and gastric aspiration. However, in those instances where further bacteriologic identification is indicated, the use of an isolated culture for guinea pig injection affords a considerable saving of time.

SUMMARY

The fluid and solid media recently described by Dubos have been successfully applied to the rapid cultivation of tubercle bacilli from pathologic material.

Of fifty-seven positive specimens examined in fluid media, fifty (87.7 per cent) were positive by culture, while fifty-four (94.6 per cent) were positive by guinea pig inoculation. Incubation periods for the positive cultures ranged from five to twenty-seven days, with a mean of 10.6 days. Forty-four (88 per cent) of the positive results were obtained within fourteen days of incubation.

Too few specimens have been examined on the solid medium to permit analysis. Four strains which failed to grow in broth grew readily on the solid medium. Colony morphology on this medium is strikingly different from that observed on coagulated egg media. Growth occurs as soft, discrete, semitransparent colonies not unlike those of the streptococci.

DISCREPANCIES IN THE AGGLUTINATION TEST FOR BRUCELLOSIS AS PERFORMED WITH VARIOUS ANTIGENS AND AS REPORTED FROM DIFFERENT LABORATORIES

C. WESLEY EISELE, NORMAN B. McCULLOUGH, AND GRACE A. BEAL
CHICAGO, ILL.

INCONSISTENCIES in the results of brucella agglutination tests when performed on the same serum with different antigens have been the cause of concern in our laboratory. Although close attention was given to uniformity and accuracy of the technical details of the test, nevertheless, significant differences in titer have been observed with disconcerting frequency when several commercial antigens were used in routine testing. Furthermore, results obtained with different lots of the same commercial antigen were not infrequently at variance with each other.

Similar experiences have been noted by others. Serum from a patient with culturally proved chronic brucellosis reported by Spink, Hall, and Aagaard¹ was sent to two different laboratories for agglutination tests. One laboratory reported that no brucella agglutinins were present; the other reported an agglutinin titer of 1:400. Angle, Algie, and Morgan² observed similar discrepancies and cite an example in which a serum was reported by a state laboratory as giving a negative test for brucella agglutinins, but on which positive tests were obtained by them in dilutions of 1:640 with three commercial antigens.

The present study was undertaken to explore the extent of the variability of brucella agglutinin titers as determined with different antigens and also as reported by different laboratories. It is an attempt to determine the deviations one might expect to encounter in actual practice under existing laboratory conditions.

PROCEDURE

Fifteen milliliters of serum were collected from each of eighteen individuals known to have moderate brucella agglutinin titers. In seven of the patients, blood cultures had been positive for *Brucella abortus* from sixteen months to seven years before, but the infection was considered to be quiescent at the time of the present tests. In one individual, brucella agglutinins had developed in response to vaccination for cholera.³ The other ten were presumed either to be suffering from chronic brucellosis or to have recovered from the disease. In addition, sera were collected from three rabbits, each of which had been infected with one of the three species of *Brucella*—*melitensis*, *abortus*, and *suis*. Because of the very high agglutinin titers of these rabbit sera, dilutions were made with normal rabbit serum to bring the titers into a more moderate range.

The opsonocytophagic test was done on the blood of each patient at the time the serum was collected. In the blood of fifteen of the patients, there was marked phagocytosis by 80 per cent or more of the leucocytes, while the other three showed moderate phagocytosis. This tends to confirm further the specific identity of the antibody response in these patients.

Each serum was collected and prepared aseptically and was divided into six lots in sterile, stoppered tubes. One tube of each serum was sent to each of five laboratories other

From the Department of Medicine, the University of Chicago.

than our own with a request for routine brucella agglutination tests. No information was given to the laboratory concerning the clinical histories, nor were the reasons for requesting these tests divulged. Two public health laboratories, two private clinical laboratories, and one veterinary laboratory were selected as representative of those commonly used in practice.

The sixth tube of each serum was tested in our own laboratory against the following ten antigens: seven commercial rapid slide antigens, one commercial test tube antigen, one test tube antigen supplied by the Bureau of Animal Industry of the U. S. Department of Agriculture, and one test tube antigen prepared in our laboratory from *Br. abortus* strain 295 in accordance with the directions of Huddleson.⁵ The eight commercial antigens were purchased on the open market and represented all those which were available to us after a thorough search of sources. Several of the specimens were not tested with all the antigens because of insufficient sera. All tests performed in our laboratory were in accordance with standard techniques.⁷

As a matter of interest, sera were similarly collected from three patients who had recently received intravenous combined typhoid vaccine for fever therapy. These sera were tested for typhoid agglutinins in our laboratory and were also submitted to five other laboratories. The same laboratories were used as for the brucella agglutination tests, except that a hospital laboratory was substituted for the veterinary laboratory.

RESULTS

The results of the brucella agglutination tests performed in our laboratory as well as those reported from the five other laboratories are presented in Table I. The table also gives the maximum and minimum values reported for each serum by the five laboratories as well as the maximum and minimum values of all fifteen tests.

In the titers reported from the five laboratories other than our own, it will be noted that of the twenty-one sera submitted, eighteen were called negative by one or more laboratories. Of these eighteen "negative sera," all except one were reported by other laboratories as positive in titers ranging from 1:100 to 1:640.

The variations of the agglutinin titers obtained in our own laboratory with the ten different antigens confirmed, in a general way, and, in a few cases, extended the magnitude of the deviations reported by the other laboratories. In our laboratory, however, only one serum was found to be negative in any test.

The variations in the brucella agglutination tests of six selected cases are presented graphically in Fig. 1.

The typhoid and paratyphoid agglutination tests that were reported on the sera from three patients treated with intravenous typhoid combined vaccine are presented in Table II. Inconsistencies in the titers reported by different laboratories are evident in these data also.

DISCUSSION

The brucella agglutination test is more widely used than any other procedure in the diagnosis of brucellosis. It is used extensively in the diagnosis of the human disease as well as being the generally accepted criterion for the presence of infection in cattle. At the first Inter-American Brucellosis Congress held in Mexico City in 1946, various speakers indicated that "the agglu-

*The maximum titer obtainable with this antigen.

tion test continues to be the most useful procedure in the diagnosis of active brucellosis.¹⁴ It is therefore of considerable importance to evaluate the reliability and accuracy of the test as it is applied in actual practice.

The significance of the agglutination test in relation to human brucellosis has long been subject to discussion, and its interpretation in terms of clinical infection may be a difficult task indeed. The question is frequently asked, what is a clinically significant titer? An unqualified answer cannot be given and a number of limitations must be considered.

Several sources of difficulty in the interpretation of the brucella agglutination test arise from biologic factors. It is well known that individuals vary markedly in their ability to produce brucella agglutinins in response to clinical infection. Also, different strains of the organism vary in their agglutinogenic power. Many authors^{1, 2, 5} have reported cases of brucellosis verified by blood cultures in which no serum agglutinins appeared. Conversely, apparently healthy individuals with significant titers in their blood are found in brucella-agglutinin surveys. Thus, blood from a patient who has brucellosis may contain no agglutinins, while blood from a symptomless individual may contain them.

It has long been known that infection with *Pasturella tularensis* produces a cross-agglutination response for brucella. Recently, we have shown that significant titers of brucella agglutinins, as well as opsonins, develop in most individuals receiving the standard two-dose cholera vaccination.³ This response is due to an H antigen of *Vibrio comma*.

In addition to the irregularities of agglutinin response arising from the uncontrollable biologic variables, the present studies demonstrate that the measurement of brucella agglutinins in any given serum is subject to great variation with the usual laboratory methods. The magnitude of this variation is such that of twenty-one sera submitted to five qualified laboratories for routine test-

ing, reports on each of eighteen varied from completely negative to positive in dilutions of 1:100 to 1:640. Two-thirds of the so-called "negative tests" were reported elsewhere as positive in dilutions of 1:320 or 1:640—titers which are considered by many physicians as substantiating a clinical diagnosis of brucellosis. Similarly, a negative test is often regarded as excluding that diagnosis. Depending on which laboratory report is accepted as the actual titer, at least two-thirds of the cases of this series can be thus either "ruled out" or "substantiated." That such blind reliance on agglutination tests is deplorable is well demonstrated by these data. Our views on the clinical interpretation of the agglutination test have been discussed in previous publications.⁶

We do not intend to imply that the brucella agglutination test is a useless procedure. If one is not indifferent to the sources of error and if one does not attempt to interpret the test too strictly, it may be a useful adjunct to diagnosis. We believe that the variations observed in this study are mainly due to a lack of standardization of the antigens. Angle, Algic, and Morgan² noted similar diversity in agglutination titers when they used antigens which they prepared from twenty stock strains of brucella. Variations of technique of the test may also be a contributing factor. The admonition of the Committee on Bang's Disease of the United States Live Stock Sanitary Association⁷ bears repeating: "The reading of tests should be carried on only by individuals who have had wide experience in this work. Extreme care should be exercised in the observation of tests to minimize the discrepancies resulting from improper or careless observation." It would appear that much of the difficulty could be avoided if standardization of all antigens were supervised by some central agency, or if standard sera were available for checking antigens. The test as used in our laboratory has given consistent results when antigens prepared from the same strain have been employed.

Limited observations on the results of typhoid and paratyphoid agglutination tests made on sera from patients treated with typhoid vaccine suggest that the variations observed in the agglutination test for brucella also occur in other agglutination tests. It is noteworthy that the agglutinin response in these patients was the result of vaccine therapy rather than of a natural infection, as was the case in the brucella sera. It should also be mentioned that inconsistencies in the testing of typhoid and paratyphoid agglutinins are of considerably less clinical importance than in the case of brucella agglutinins. In comparison with brucellosis, the agglutination test plays a relatively minor role in the diagnosis of the enteric infections.

SUMMARY

1. Wide variations in brucella agglutinin titers were observed in each of twenty-one sera tested with ten different antigens in our laboratory. Tests on the same sera made in five other laboratories showed equally great discrepancies.

2. Of the twenty-one sera tested, eighteen were called negative by one or more laboratories. Of these eighteen "negative sera," sixteen, or 89 per cent, were elsewhere called positive in titers of 1:200 or higher; twelve, or

67 per cent, were called positive in dilutions of 1:320 or 1:640—titers which are frequently considered as substantiating a clinical diagnosis of brucellosis.

3. Depending on which laboratory report is accepted as the actual titer, two-thirds of the eighteen cases can be either "ruled out" or "substantiated" by commonly accepted but deplorable practices of interpretation of the test.

4. Limited observations on typhoid and paratyphoid agglutination tests suggest that the variations observed in the tests for brucella also occur in other tests.

HUMAN BRUCELLA MELITENSIS INFECTIONS IN MINNESOTA WITH HOGS AS THE PROBABLE SOURCE

PAUL KABLER, M.D., PH.D.,* HENRY BAUER, M.S.,* AND
C. BARTON NELSON, M.D., M.P.H.†
MINNEAPOLIS, MINN.

THREE species of the genus *Brucella*, *abortus*, *melitensis*, and *suis*, are recognized as the etiologic agents causing brucellosis in man and animals. *Brucella abortus* and *Brucella suis*, etiologic agents for brucellosis in cattle and hogs, respectively, have been recognized in Minnesota since laboratory diagnosis was begun. The *melitensis* species, usual incitant of brucellosis in sheep and goats, has not previously been established as present in man or livestock in this state.

Kabler and MacLanahan¹ in 1936 reported on forty strains of *Brucella* isolated in Minnesota from human cases of brucellosis. They classified these strains as follows: twenty-five strains of *Br. suis*, thirteen strains of *Br. abortus*, and two strains with conflicting reactions, one of which appeared to be *Br. suis* and the other *Br. melitensis*.

Jordan and Borts² in 1946 reported the isolation of twenty-six strains of *Br. melitensis* in Iowa from human cases of brucellosis. One strain was isolated in 1930, and twenty-five strains have been isolated since December, 1943.

The present report, based on laboratory findings and epidemiologic investigations made in 1945-1946 by the Minnesota Department of Health, deals primarily with thirteen strains of *Br. melitensis* isolated from human cases of brucellosis.

MATERIALS AND METHODS

Blood Culture.—Twenty-five milliliters of bacto-tryptose broth, pH 6.8, containing 1 per cent sodium citrate, were placed in a 2-ounce rubber diaphragm screw-capped bottle and sterilized. A lead foil cover was placed over the cap and crimped tightly around the neck of the bottle. The bottle was then mailed to the physician with the instructions to draw, aseptically, 5 ml. of blood from the patient during a febrile attack, to insert the needle through the diaphragm of the cap and expel the blood from the syringe into the broth, replace the lead foil over the cap of the bottle, and return the bottle to the laboratory by mail.

Upon receipt of the culture in the laboratory, approximately 10 per cent of the air was aseptically removed from the bottle and replaced with an equal volume of CO₂. The broth culture was then incubated at 37° C. After five days of incubation, four tubes of bacto-tryptose agar, pH 6.8, were inoculated, each tube receiving approximately 1 ml. of broth culture. Two tubes were incubated aerobically at 37° C. and two tubes in an atmosphere of 10 per cent CO₂. The broth culture was returned to the 37° C. incubator for another ten days, after which time four more tryptose agar slants were inoculated and incubated as previously described. Each set of subcultures was observed every other day for a period of two weeks. No blood cultures were discarded as negative before thirty days.

From the Minnesota Department of Health.
Received for publication, April 21, 1947.

*Section of Medical Laboratories.

†Section of Preventable Diseases.

Brucella species were identified according to their CO₂ requirements, staining reactions, fermentation reactions, bacteriostatic action of dye plates, H₂S formation as described by Huddleson and co-workers,³ and serologic tests.

Agglutinations.—Macroscopic tube agglutination tests for the presence of *Brucella* agglutinins were made with serum obtained from clotted whole blood specimens submitted by the attending physician.

LABORATORY AND EPIDEMIOLOGIC DATA

During the years of 1945 and 1946, a total of 193 *Brucella* strains were recovered from human sources. Of these strains, 165 (84.5 per cent) were *Br. abortus*, 15 (7.8 per cent) were *Br. suis*, and 13 (6.7 per cent) were *Br. melitensis*.

The results of the laboratory tests and the epidemiologic findings of the thirteen human cases of brucellosis due to *Br. melitensis* are summarized in Table I.

TABLE I. THIRTEEN CASES OF HUMAN BRUCELLOSIS DUE TO *Br. melitensis*: SUMMARY OF LABORATORY FINDINGS AND EPIDEMIOLOGIC DATA

CASE	INITIALS	AGE	AGGLUTINATION REACTION		POSITIVE BLOOD CULTURES DATE RECEIVED	ANIMAL CONTACT		PROBABLE SOURCE OF INFECTION
			DATE RECEIVED	TITER		HOGS	CATTLE	
1	G. D.	53	2/13/45	1:2560	2/16/45	Yes	No	Packing plant, handling hog salvage
2	C. H.	49	3/26/45	1:2560	3/28/45	Yes	No	Packing plant, handling hog casings
3	W. F.	40	3/31/45	1:320	4/ 3/45	Yes	No	Packing plant, handling hog casings
4	M. P.	19	4/30/45	1:5120	5/23/45	Yes	No	Packing plant, handling hog casings
5	W. K.	50	5/10/45	1:1280	5/13/45	Yes	No	Packing plant, lard making
6	K. D.	29	6/ 8/45	1:5120	6/21/45	Yes	No	Packing plant, hog kill
7	R. B.	20	6/21/45	1:1280	6/24/45	Yes	No	Packing plant, hog kill
8	L. J.	29	7/13/45	1:640	7/20/45	Yes	No	Packing plant, pork trim
9	R. C.	25	9/11/45	1:160	9/20/45	Yes	No	Packing plant, shackling hogs
10	C. H.	34	5/ 2/46	1:5120	5/15/46	Yes	Yes	Farm abortion in hogs (cows nonreactors)
11	I. S.	51	6/19/46	1:2560	6/21/46	Yes	No	Packing plant, hog kill
12	L. H.	30	7/ 6/46	1:5120	7/14/46	Yes	Yes	Farm, handling aborted material from hogs (no history of abortion in cattle)
13	R. D.	35	7/30/46	1:5120	8/ 3/46	Yes	No	Packing plant, shackling hogs

All the cases presented in Table I are men; the youngest was 19 years of age, and the oldest 53 years. All had symptoms consistent with the diagnosis of brucellosis. Eleven of the thirteen patients were packing plant employees who handled either live hogs or pork products. Six of the employees handled the hogs at the time of killing, and four handled the pork within forty-five minutes of the killing. One employee, a pork trimmer, handled the pork the day after the animal was killed.

It is noteworthy that all the thirteen patients were residents of four Minnesota counties that border the northern section of Iowa. Two were farmers,

both of whom owned hogs bred and raised locally which aborted. There was no history of abortion in the cattle on either of these farms. Unpasteurized cow's milk was used by two of the thirteen patients; and one obtained raw milk from a cow that gave a negative reaction when tested for Bang's disease.

The hogs handled at the packing plant all came from Minnesota or from points in Iowa, and North and South Dakota, which are readily accessible by truck and rail to the Minnesota market.

COMMENTS

The isolation of *Br. melitensis* from the blood of persons in southern Minnesota demonstrates this organism as being endemic in this area.

Br. melitensis was originally regarded as the etiologic agent of brucellosis in sheep and goats, and it was believed that these animals act as reservoirs for this organism; however, there is evidence^{4, 5} that all species of *Brucella* may infect cows, hogs, sheep, or goats. That hogs are susceptible to *Br. melitensis* is indicated in the statement by Huddleson³: "Melitensis is pathogenic for the hog. While I was in Malta in 1938, I saw evidence of its pathogenicity. A considerable amount of left-over unpasteurized goat's milk was fed to a group of pregnant sows. All of them aborted. *Melitensis* was recovered from the fetuses. For some reason this observation was never reported in the literature."

In the series of cases presented in this report, there is no history of contact with sheep or goats. The epidemiologic findings show that all patients had direct contact with hogs; in two cases there was contact with cattle in which there was no history of Bang's disease.

SUMMARY

1. *Br. melitensis* has been isolated from blood cultures of thirteen human cases of brucellosis.

2. All the patients were men having direct contact with hogs; eleven were packing plant employees and two were farmers.

3. Epidemiologic studies of *Br. melitensis* infections incriminate hogs as the source of infection; in at least two of the cases, the hogs were bred and raised in Minnesota.

4. All human cases of brucellosis due to *Br. melitensis* that have been detected to date are residents of four counties in south-central Minnesota.

THE DIFFRACTION METHOD OF MEASURING RED BLOOD CELLS

ADRIANUS PIJPER, M.D., D.Sc.

PRETORIA, SOUTH AFRICA

THE history of the diffraction method of measuring red blood cells is a story of a lucky accident. It is only because of a mistake by a technical assistant that the method is in use today and has been able to make its contribution to medical science both by stimulating investigations into the diameters of red cells and as a diagnostic method. In 1918 I planted a drop of centrifuged urine into clear broth. Next morning there was a faint haziness, indicating bacterial growth, but on shaking the bottle, a small number of glittering small particles became detached from the bottom. They whirled through the liquid and exhibited a bluish-greenish radiance. Thinking I had found a new color-producing microbe, I made subcultures on agar. A variety of colonies developed, none of them obviously colored. One evening, having another look at the colonies, I moved the Petri dish up and down in front of an electric light bulb. It was then that I noticed that some colonies exhibited a curious colored gloss, in which bluish green predominated, with a faint suggestion of the other colors of the spectrum. (This phenomenon, once one knows of it, can easily be seen in thin surface cultures of many bacteria if one holds the culture between the eye and a bright source of light, preferably in a darkroom. It is what textbooks sometimes vaguely call "iridescence.") These colonies turned out to be ordinary staphylococci, but since the color phenomenon persisted in subcultures, I started making extracts of them with various solvents, hoping to isolate the elusive coloring substance. I failed in this, and then it dawned upon me that the phenomenon might be physical and not chemical. I first thought of fluorescence and then suddenly realized that I was dealing with diffraction of light, the surface culture acting as a diffraction grating. I went back to the original broth culture and found that the shiny particles were powdered glass and had nothing to do with the phenomenon, having merely found their way into the broth through a mistake of a technical assistant. (We had been using powdered glass for estimations of atmospheric bacteria, following a method then in vogue.) In pursuance of the idea that diffraction was the cause of the phenomenon, an apparatus was constructed in which a beam of white light was sent through a surface culture of staphylococci, and the resulting diffraction colors were collected and focused onto a screen.¹⁹ A formula was developed enabling one to calculate the diameter of the cocci from the diameter of the diffraction spectra. By substituting a culture of round monilias for the cocci, a check was obtained on the correctness of the formula.¹⁹ I then considered that the principle of diffraction, which, should also work with round
lls.²⁰⁻²² It is shown in Fig. 1

how a beam of white light, sent through thin end of a blood film, undergoes diffraction at the edges of the red cells and produces sets of colored rings, arranged in rainbow or spectrum fashion and sometimes called halos. This is the origin of all diffraction methods for measuring red blood cells now in use.*

It is shown in Fig. 1, and similarly in Figs. 2 and 3, that there is only one "complete" spectrum where all the colors are easily discernible. This is the spectrum to be used for measurements and comparison.

In the following years little scientific notice was taken of this method, except by Bergansius,² Millar,¹⁸ Ponder,^{35, 36} and Allen and Ponder.¹ During this time the technique was improved and applied to the measurement of various bacteria.^{24-26, 28} It was not until 1924 that, stimulated by a publication of Hurst¹³ on anemias, I applied the method to the differential diagnosis of anemias²³ and to their follow-up.²⁹ Various authors and firms then produced a variety of instruments for applying the method. Emmons⁷ brought out the clinical eriometer. Eve⁸ built a halometer which became strangely popular and which was followed by the direct halometer to which a Dr. Fine's name was attached. Pryce⁴² simplified the halo method; Edwards⁶ built a simple box of his own; Menzies¹⁷ used a new refractometer (sic) designed by Dr. Malloy; Renshaw and associates⁴³ spoke of a hemovisor they were planning; and Bock⁴ introduced the erythrocytometer which became widely used on the continent of Europe. Fullerton and co-workers¹⁹ used an apparatus of their own and also a Ewles halometer. Christophers and Craighead⁵ suggested an ingenious micromethod which employed a microscope, and Falisi¹⁰ on similar lines produced a micro-diffractometer that was followed again by Smith¹⁵ who introduced a diffractometer manufactured by the Spencer Lens Company which appears to work well, although in common with all the methods and apparatuses mentioned, it does not allow direct comparison of two blood films. Schalm¹¹ had a pocket apparatus built by Zeiss; Hogben¹⁴ constructed an apparatus of his own; and finally there is Haden's¹² Haden-Hausser erythrocytometer. This list is probably not complete; it is likely that there are further variations of the same theme still unknown to me.

An improvement in technique came in 1929 when comparison was made in one apparatus of the diffraction patterns of two different blood films.^{30, 31} This was done by cutting off one half of the set of colored circles produced by each of the two films and making the remaining semicircles share the same middle-line on the receiving screen. The arrangement in diagrammatic fashion is shown in Fig. 2. This allows direct comparison of an "abnormal" with a "normal" blood film, thus doing away with the need for actual measurement in many cases, simple inspection of the two diffraction patterns being sufficient to get the required information. This design also provides for direct comparison of two blood films taken from the same patient at different times, a very useful feature in the follow-up of patients. An apparatus on these lines can easily be put together by a technical assistant. Eventually this improved technique was em-

*It was later brought to my notice that Young³⁸ in 1813 applied the same principle to the measurement of wool fibers (eriometer) and later of red blood cells. His work was never followed up.

FIG. 1.

FIG. 2.

Fig. 1.—Diagram of blood film serving as diffraction grating.
Fig. 2.—Diagram of apparatus, known as Piper's Blood Cell Tester. Direct comparison of two blood films, normal or standard blood film on one side, pernicious anemia on the other.

Fig. 3.—What appears on screen of apparatus when normal or standard blood is compared with anemia caused by prolonged hemorrhages, malignant growth, or similar conditions. Spectrum on right is broader, but yellow circle is not displaced. This means normal mean diameter with increased anisocytosis.

bodied in the apparatus placed on the market in 1935 by Zeiss as Pijper's Blood Cell Tester.¹³⁻¹⁴ Its shape and size are the result of cooperation between Prof. Siedentopf, technical adviser to the Zeiss firm, and myself. It is based on the idea illustrated in Fig. 2. Pictures of it can be found in some textbooks.¹⁵ In Fig. 2 the spectra produced by a normal blood film and a blood film from a case of pernicious anemia are compared. In Fig. 3 is shown what actually appears on the ground-glass screen of the cell tester when normal blood and blood from a case of anemia caused by prolonged hemorrhage, malignant growth, or similar conditions are compared.

PURPOSE OF PAPER

The purpose of this paper is to show that, contrary to what is usually stated in textbooks and other publications, the diffraction method of measuring red cells, if properly applied, is capable not only of determining the mean diameter of about one million cells, but also of determining the degree and quality of anisocytosis present in a blood film. A good diffraction apparatus should allow three measurements or determinations. One gives the mean diameter, the second gives the diameter of the smallest cells present in appreciable numbers, and the third does the same for the largest cells. All this can be done in a few minutes and in this way degree and quality of anisocytosis are determined. I do not know of any other apparatus that is capable of doing this. The technical side of this paper therefore applies to the apparatus known as Pijper's Blood Cell Tester or to any apparatus built on identical lines.¹⁶

IMPORTANCE OF DETERMINING RED CELL DIAMETERS

Modern hematology emphasizes morphology. Importance is attached to shape and size of red blood cells. Hematology owes a good deal to the careful microscopie measurements of red cells by Price-Jones and associates.¹⁷⁻²¹ This work brought revelations, but apart from an occasional special case, Price-Jones' method and its substitutes are too elaborate for daily application.

The old-fashioned determination of the hemoglobin index as an indication of the size of the red cell still lingers on. This is indefensible because its value is arrived at by dividing a hemoglobin value by a red cell value, neither of which is usually determined with sufficient accuracy. It is admitted that by using a photoelectric colorimeter, errors in hemoglobin estimations can be very much reduced, but there is no similar reliable method yet for red cell counts. It is known that in ordinary work, with the apparatus available in most laboratories, an error of 5 per cent in both these determinations is unavoidable, an error of 10 per cent is quite common, and higher errors occur. A calculation based on two incorrect values should in principle be avoided as it leads to still more erroneous final results. What may happen, unless particular care is taken, is illustrated in Table I

*At the present time, as far as I know, no blood cell testers can be obtained from the Zeiss firm. Perhaps an American firm will find it worth while to build an apparatus on the same lines and of identical dimensions, so that the numerical data supplied in this paper will apply.

TABLE I. ERRORS IN DETERMINATION OF HEMOGLOBIN COLOR INDEX

	HEMOGLOBIN (PER CENT)	RED CELLS	INDEX
Supposed real values	90.0	4.0	1.1
Errors of 5 per cent	85.5	4.2	1.0
Errors of 5 per cent	94.5	3.8	1.2
Errors of 10 per cent	81.0	4.4	0.9
Errors of 10 per cent	99.0	3.6	1.4

It is seen that through errors often accompanying the method, an index which in reality is 1.1 can appear as high as 1.4 or as low as 0.9. Index determinations therefore are inadvisable.

Similar objections can be raised against determinations of mean red cell volume by dividing hematocrit values by number of cells. What may happen, unless particular care is taken, is illustrated in Table II.

TABLE II. ERRORS IN DETERMINATION OF MEAN CELL VOLUME

	VOLUME OF PACKED CELLS (PER CENT)	NUMBER OF RED CELLS	MEAN CELL VOLUME
Supposed real values	39.2	3.80	103
Errors of 5 per cent	41.1	3.61	114
Errors of 5 per cent	37.3	3.99	93
Errors of 10 per cent	43.1	3.42	126
Errors of 10 per cent	35.3	4.18	84

It is seen that in a case where the mean red cell volume in reality is 103, errors often accompanying the method may lead to erroneous determinations as high as 126 or as low as 84.

There is, of course, nothing new in this criticism; many authors admit the shortcomings of these methods (Todd and Sanford⁴⁶ and Wintrobe⁴⁹). In experienced hands the method for determination of mean red cell volume still works reasonably well, but many workers do not seem to be conscious of the fundamental fact that it is unsatisfactory to try and arrive at a correct value by dividing two incorrect values one by the other. The problem confronting hematologists nowadays is not only to place obvious cases into the correct category, but to deal with and to follow up early and mild cases in a satisfactory manner. These are the cases where deviation from the normal may be minimal, and in such cases involved calculations on not very accurate data may become misleading. There are, for example, cases of early subacute-combined degeneration of the cord, and cases of mental changes due to early pernicious anemia as described by Warburg and Jørgensen,^{47, 48} where hemoglobin and red cells show too little change to lead to reliable results in the determination of either hemoglobin index or mean cell volume. There, in my experience, a direct determination of red cell diameter by the diffraction method may definitely show a quick way to the correct diagnosis.

THEORY OF DIFFRACTION METHOD

Even professional physicists admit great difficulties in attempts to give a full explanation as to what happens when a beam of light passes through a blood

film. The following formula, which applies to the conditions of Figs. 1 and 2, has, however, found favor among physicists and answers well in practice.

$$\text{Diameter red cells} = \frac{1.7 \lambda \sqrt{f^2 \times r^2}}{r}$$

In this formula " λ " is the wave length of light under consideration, " f " is the focal distance of the lens (L) in Figs. 1 and 2 which focuses the diffraction pattern on the screen (S), and " r " is the radius of the colored circle of wave length " λ ."

In the blood cell tester the lens has a focal distance of 20 cm., and " r " varies between 1.5 to 3.5 cm. As " r " is so much smaller than " f ," the formula can be simplified by eliminating " r^2 ." A simple calculation will show that the average error introduced thereby is not more than 1 per cent, which is within the experimental error of the method. The formula thus becomes:

$$\text{Diameter red cells} = \frac{340,000 \lambda}{r}$$

The colored circles which are of importance are those of yellow, outer edge of red, and innermost violet. This means one color rather near the middle of the spectrum and two others at the extreme ends of the spectrum. Yellow is chosen because it is a narrow band, and therefore easy to read, and quite near enough the middle of the spectrum to be suitable.

The position would be very simple if all red blood cells in a given film were of identical diameter. This is not the case in normal blood, and less so in abnormal blood. Price-Jones³⁷⁻⁴⁰ has shown that red blood cells form a population and their size distribution follows a frequency curve. There are kinds of anemia where this curve is a good deal flatter than normal, in other words where the only abnormality is an increased degree of anisocytosis. Normal blood has cells of a mean diameter of about 7.5 microns, but through normal anisocytosis there is an ever-decreasing number of smaller and larger cells.

If all red blood cells in a given film were of identical diameter, it would not matter which color was chosen for applying the formula, the result would be the same in any case. The position which arises from the ever-present anisocytosis is illustrated in Fig. 4.

Shown in Fig. 4 in the left top quadrant are the three main colored circles resulting from a normal blood film as produced by diffraction by the cells of 7.5 microns, which are the most numerous ones and therefore produce the brightest colors. In a normal film the anisocytotic spread will comprise cells from 7.5 to about 6.7 microns, on the one side, and cells from 7.5 to about 8.5 microns, on the other side. In the bottom left quadrant of Fig. 4 are shown the colors produced by the largest cells, and in the top right quadrant the colors produced by the smallest cells. In actual practice of course the three sets of colored rings are superimposed, giving rise to the bottom right quadrant.

It is seen that the final position of the yellow ring is hardly affected by the superimposition of the diffraction patterns of all the red cells. It therefore

can safely be used for the calculation by means of the formula of the mean diameter of all the red cells.

It is also obvious that in the final spectrum the outer edge of the red circle is the expression of the diameter of the smallest cells in the film, and the innermost violet circle the expression of the diameter of the largest cells. These colored circles thus can be safely used in the formula for the calculation of the smallest and largest cells present. Application of the formula three times, once for yellow, once for red, and once for violet, gives the mean diameter and the smallest and largest cells, in other words, the kind and degree of anisocytosis present.

It should now be clear that any diffraction method which bases its measurements on anything but the yellow circle for the calculation of mean diameter is faulty. A measurement based on the position of the outer edge of the red circle, as is often done, will result in calculating not the mean diameter, but the diameter of the smallest cells. In normal blood this may not make much difference, as the values for mean diameter and smallest diameter lie close together. But in cases where anisocytosis is increased, and there are cases where increased anisocytosis is the main or even only abnormal feature, a serious error will be committed. Increased anisocytosis means a broader total spectrum, the distance between the outer edge of the red ring and the innermost violet ring being larger than normal. It is one of the advantages of the cell tester that such an increase in anisocytosis can be read at a glance, through the direct comparison with normal blood (Fig. 3).

TECHNIQUE OF READING RESULTS AND MEASURING

The essence of good work with blood films for any purpose is even distribution of cellular elements over a glass surface. Measurements, whether by microscopic methods or by diffraction, can only be reliable if the red cells lie separate over a large area. Any diffraction method needs a circular area of this kind of at least a quarter of an inch in diameter. If there are many cells lying partly on top of one another, one does not measure the diameter of single cells, and the results will be vitiated. A properly made blood film, made by pushing the polished narrow edge of a microscope slide along the surface of another microscope slide, with a drop of blood inside the angle made by the two slides, shows a silky glossy area at the end of the film. The speed of the movement and the size of the angle determine the quality of the film; practice is essential to acquire the art. It is only the silky area at the end of the film that can be used for diffraction measurements (Fig. 5). A simple way of checking on the suitability of a blood film is to look through its thin silky end at a distant lamp. One should then see a number of bright rainbows round the lamp. It is only with pronounced poikilocytosis that the rainbows are not so bright.

The film is moved about on the stage of the apparatus over the little hole which admits the light until one has found the spot which produces the brightest and clearest colors. This is a matter of experience.

On the screen of a properly designed apparatus for the diffraction measurement of red blood cells, such as the blood cell tester, one sees two sets of con-

Fig. 4.—Superposition of spectral rings produced by the varying diameters of the red blood cells in a normal film.

centric colored circles arranged in rainbow fashion, as in Fig. 3. Starting from the center, where a bright patch of white light is covered by a small black shield, and traveling to the periphery, one first goes through a reddish-brown circle. Then follows the violet of the spectrum that is used for measurement and comparison. The further colors of the rainbow appear in orderly fashion, blue, green, yellow, orange, and red. The red circle is surrounded by a green circle, which belongs to the next spectrum and which for reasons into which I need not go now is somewhat confused. After this green there may be another red circle, followed again by green, and so on. For purposes of measurement and comparison one need only to take notice of the complete spectrum ranging from the innermost violet to the outer edge of red. In Fig. 3 it is at once obvious that the total spectrum on the right-hand side is a good deal wider than the one on the left. The one on the left is produced by a normal blood film and serves as a standard. There are minor individual variations in what is usually regarded as normal blood, but as a rule a properly prepared blood film made from a healthy person with a hemoglobin content of over 15 Gm. per 100 ml. will serve.

Fig. 5.—Properly made blood film, the thin silky area at the end to be used.

Such a standard blood film, unfixed and unstained, will remain serviceable for many months. In Fig. 3 it is further noticed that the yellow circle on the right side, produced by the blood under examination, is of about the same width as that of the standard blood on the left. The yellow circle being the expression of the mean diameter of the red blood cells, it becomes obvious that the mean diameter of the red blood cells under examination can be regarded as normal. If absolute values for this mean diameter are desired, a pair of compasses is used, placing the sharp point of one of the legs on the yellow circle where it touches the black line dividing the two sets of colored circles, and then the sharp point of the other leg across the center on the opposite section of the yellow circle. The distance between the two ends of the compasses is then measured on a millimeter rule and the value found converted into microns by means of the conversion table (Table III) which is based on the formula previously given. For the mean diameter one uses the column in Table III marked Yellow. If, for example, the value found in millimeters is 54, this corresponds in the conversion table to a value of 7.5 microns for the mean diameter. With practice this procedure can be performed with an accuracy of 1 mm., which corresponds to 0.1 or 0.2 microns.

The extreme edge of the red circle is the expression of the diameter of the smallest cells present in appreciable numbers in the blood film. In Fig. 3 the spectrum on the right-hand side shows that this edge extends much farther outward than with the normal blood on the left-hand side. This means that there is increased anisocytosis in the blood under examination, and this is confirmed by the innermost violet circle which is the expression of the diameter of the largest cells present in appreciable numbers and which is situated much farther inwards than in the case of the normal blood. For absolute measurements one proceeds as follows. For the extreme edge of the red circle place the sharp points of the compasses where the green circle which surrounds the extreme edge of the red one just begins, so as to make sure that the extreme edge of the red circle where the red color is faint is really taken into account. For the innermost violet, measure as near the brownish-red inner circle as possible. The millimeter values found are transferred to a millimeter rule and converted into microns by means of the conversion table (Table III), using the appropriate columns for Red and Violet. Here, too, the error should not exceed 1 mm., which corresponds to an accuracy of 0.1 or 0.2 micron. In extreme cases the error becomes larger, but also proportionally less important.

TABLE III. CONVERSION TABLE

RING IN MILLIMETERS	CELL DIAMETERS IN MICRONS			RING IN MILLI- METERS	CELL DIAMETERS IN MICRONS		
	YELLOW	VIOLET	RED		YELLOW	VIOLET	RED
25	10.5	11.7	18.3	54	7.5	5.3	8.3

53	7.6	5.4	8.5				

Conversion table to be used in connection with Pijper's Blood Cell Tester, or any other which uses a lens of 20 cm. focal distance. The diameters of the colored st and complete spectrum are given in millimeters, and from these the found in the table. Thus, a yellow ring of 54 mm. would mean a mean microns; a red ring of 64 mm. would mean that the smallest cells present in appreciable numbers would measure 7.0 microns; and a violet ring of 36 mm. would mean that the largest cells present in appreciable numbers would measure 8.0 microns.

The directions for reading and measuring and the conversion table (Table III) given here are based on theoretical considerations, amplified by long experience and supported by actual comparison of results obtained by direct microscopic methods and the diffraction method.

CLINICAL APPLICATIONS OF DIFFRACTION METHOD AND COMPARISON WITH MICROSCOPIC MEASUREMENTS

A comparison of the results of direct microscopic measurements with the results of the diffraction method applied to a small number of cases has been published.³² It was found that the results corresponded quite well. Similar work, but in less detail, has been undertaken with essentially the same results by Bernstein,³ Smith,⁴⁵ Knoche,¹⁸ and especially Haden.^{11, 12}

I have now collected a large number of cases with two sets of measurements undertaken on the same blood film, one by the diffraction method as detailed in this paper and one by fixing and staining the cells and then measuring them with the filar micrometer eyepiece of Bausch and Lomb. With the microscopic method 500 cells were measured in every case, taking the cells as they came, avoiding any temptation toward selection. The results of the microscopic measurements were then plotted in the form of a Price-Jones curve. These are given in Figs. 6 to 48, and underneath each curve the results of the diffraction measurements are given by three crosses. The middle cross indicates the mean diameter, and the other two indicate the diameters of the largest and smallest cells present in appreciable numbers. From the position of the crosses one can read off the degree and kind of anisocytosis present.

It cannot be expected that complete correspondence will be reached in all cases. The shape of a Price-Jones curve is the expression not only of variation in cell diameter, but also of variation in error committed in the computation of cell diameter. In addition, there is the "personal equation." It is my experience that no two technical assistants will return the same curve from one and the same blood film. The personal equation counts for much less with the diffraction method if it is performed as described herein, because there always is the direct comparison with normal blood. It follows from the nature of the diffraction method that the very smallest and the very largest cells are lost sight of, their number being too small to produce an appreciable amount of color. On the other hand, the diffraction method deals with at least a million cells, as against a few hundred dealt with by microscopic measurements, and with the diffraction method "selection" is excluded.

The diffraction method requires experience and good color vision, especially where through extensive anisocytosis the colors are spread over a larger area and become somewhat thin. Microscopic measurements, however, demand similar qualities. Checking results is easy with the diffraction method because it works so quickly, but it is hardly feasible with microscopic measurements without wasting an enormous amount of time. Marked poikilocytosis naturally causes watery spectra, somewhat difficult to measure, but then there always is the direct comparison with normal blood. Nobody who has tried it can be very

satisfied with microscopic measurements in such a case. A case of pronounced pernicious anemia may through poikilocytosis give an initial blood film with a very small spectrum and poorly defined colors, but this as such already represents useful information. It becomes even more useful if after a week's treatment, the colors, in films prepared then, become more defined; if the two films are then placed side by side in the apparatus, even minor improvements in poikilocytosis can be read at a glance. One can repeatedly collect films from such a patient and directly compare them in succession with one another in the apparatus and so get a complete picture of the progress of the case.

Figs. 6 to 48 refer to a selection of cases in which red cell measurements were undertaken on blood films, both by the diffraction method and by microscopic measurement.

Figs. 49 and 50 illustrate how cases can be followed by means of the diffraction method. Each horizontal line gives the cell diameters of a patient on a particular day, the three crosses representing, respectively, the mean diameter (middle cross) and the smallest and largest cells (the other two crosses). The values can be read off in microns. The first 8 lines marked PA 1 refer to a patient with pernicious anemia and give the cell diameters in consecutive weeks, the first line indicating the position before treatment started, the second line after one week's treatment, and so on, until after seven weeks more or less normal conditions are reached. The difference after one week was already striking, and the improvement continued every week. The larger cells showed a more rapid return to normal than did the mean diameter, and the mean diameter again changed more quickly and markedly than the smallest cells.

The following five lines, marked PA 2, in similar fashion refer to another patient with pernicious anemia, except that the first interval here was only four days, the other intervals again being a full week. Obvious improvement took place within the short time of four days' treatment, which was continued during the further weeks. Examinations stopped before full restoration was reached.

The next seven lines, marked PA 3, refer to a patient with pernicious anemia who was examined every week. Improvement was quite definite after one week, and more so after a fortnight, but then the patient neglected treatment for two weeks; this is reflected in the cell diameters, the cells increasing again in size, with anisocytosis becoming more marked. Treatment was instituted again, and improvement in cell diameters was again achieved, but the patient responded poorly and progress was not satisfactory, as shown by the cell diameters.

The lines and crosses marked PA 4, PA 5, PA 6, PA 7, PA 8, and PA 9 all refer to patients with pernicious anemia who were not followed for comparably long periods; the intervals between the separate individual observations varied between a fortnight and three weeks. Case PA 8 neglected treatment and this becomes manifest in the cell diameters.

These further observations confirm that at every control examination during progress it is always the largest cells that show the biggest relative improve-

Figs. 6-13.—Lee-Jones curves of various blood films, with the results of diffraction measurements indicated by crosses underneath.

Fig. 6.—Old case of pernicious anemia; treatment recently neglected. Hemoglobin, 11.6 Gm.; red cells, 1.6 million. Correspondence between two methods of measurement quite good. Just as in several of the following figures, it is noticeable that the diffraction method missed the very small and the very large cells which were present in very small numbers anyhow.

Fig. 7.—Same case as in Fig. 6, but now had had good treatment for four months. Hemoglobin, 11.5 Gm.; red cells, 5.2 million. Correspondence between two methods not so good, but "shift to left" and decrease in anisocytosis obvious by both methods.

Fig. 8.—Uninticated case of pernicious anemia. Hemoglobin, 8.2 Gm.; red cells, 2.9 million. Correspondence quite good.

Fig. 9.—Same case as in Fig. 8; had now had treatment for two months. Hemoglobin, 13.1 Gm.; red cells, 5.5 million. Correspondence good; anisocytosis more pronounced with diffraction method than with microscope method.

Fig. 10.—An Indian man, with carcinoma of liver. Hemoglobin, 4.4 Gm.; red cells, 1.3 million. Note "shift to right" and very marked anisocytosis brought out by both methods.

Fig. 11.—Pernicious anemia, untreated. Hemoglobin, 6.1 Gm.; red cells, 1.6 million. Both methods showed very similar conditions of red cells; the diffraction method showed more anisocytosis.

Fig. 12.—Pernicious anemia, untreated. Hemoglobin, 4.4 Gm.; red cells, 2.0 million. Correspondence quite good, except for some more smaller cells showing up by microscopic method.

Fig. 13.—Same case as in Fig. 12, but now had had several treatments for several weeks. Hemoglobin, 9.9 Gm.; red cells, 3.7 million. Note "shift to left," but cells still remained large and anisocytosis very marked.

Fig. 14.—Pernicious anemia. Hemoglobin, 6.7 Gm.; red cells, 2.8 million. Correspondence good except for some smaller cells, which had got lost with the diffraction method. In essence, however, both methods agree quite well.

Fig. 15.—Same case as in Fig. 14, but now had had treatment for two weeks. Hemoglobin, 9.7 Gm.; red cells, 3.7 million. Identical "shift to left" coming to light by both methods. Cells still remained large and anisocytosis very marked.

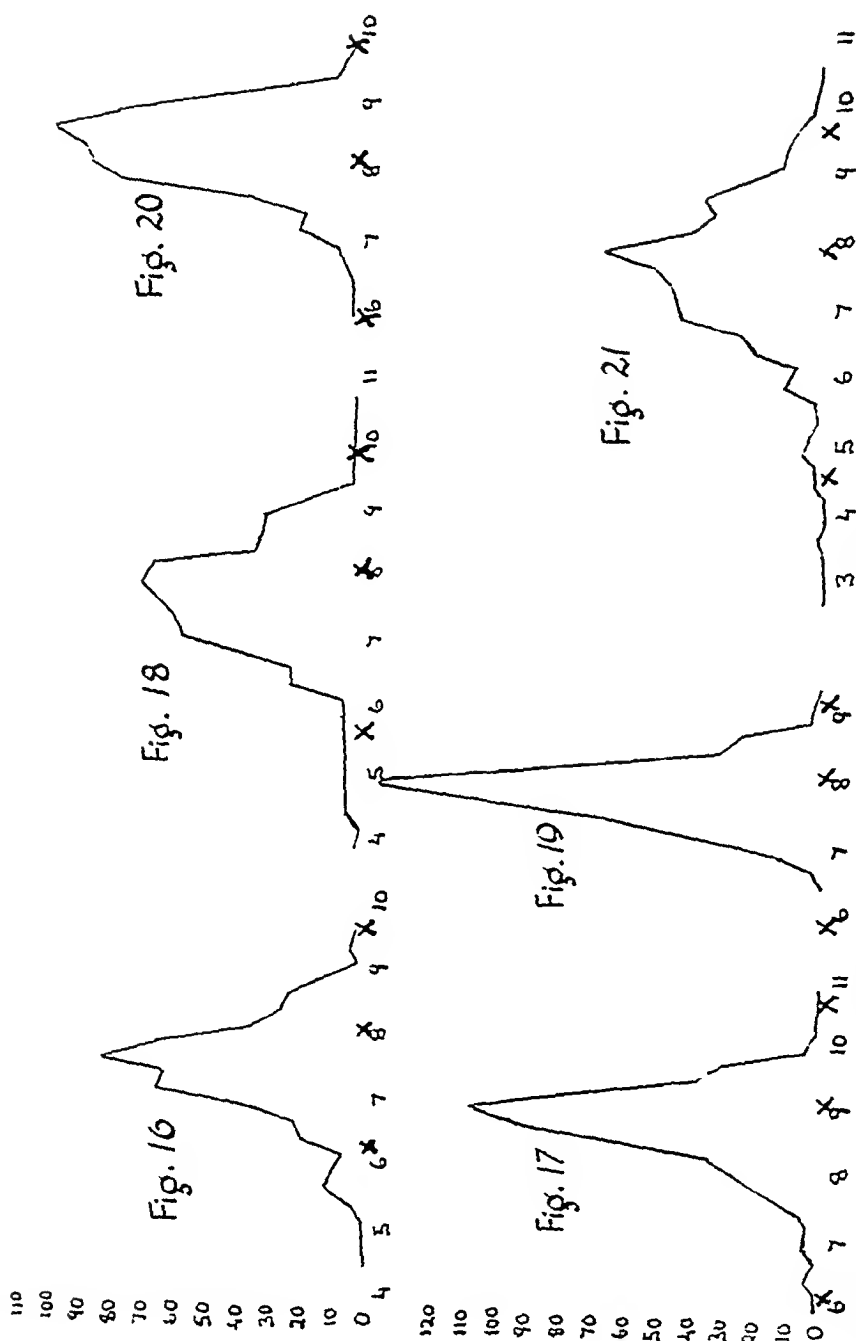

FIG. 16.—Same case as in Figs. 11 and 15, but now had had six weeks of treatment. Hemoglobin, 11 Gm.; red cells, 5.1 million. Cells still rather too large and too much anisocytosis, both abnormalities up to now more pronounced with diffraction method.

FIG. 17.—Pericious anemia; had had irregular treatment. Hemoglobin, 12.6 Gm.; red cells, 1.7 million. Cells still much too large, anisocytosis more than normal, both changes more obvious with diffraction method.

FIG. 18.—Insufficiently treated pernicious anemia. Hemoglobin, 5.1 Gm.; red cells, 2.6 million. Note marked anisocytosis and large cells, as shown by both methods.

FIG. 19.—Subacute combined degeneration of spinal cord. Hemoglobin, 13.9 Gm.; red cells, 5.7 million. Note large cells with hardly more anisocytosis than normal. This is the kind of case that is quickly diagnosed by diffraction method.

FIG. 20.—Obscure jaundice in child. Hemoglobin, 14.3 Gm.; red cells, 5.3 million. Cells large, with marked anisocytosis, rather similar picture by both methods.

FIG. 21.—Pernicious anemia. Hemoglobin, 5.9 Gm.; red cells, 2.0 million. Correspondence very good.

Fig. 41.—Obscure liver disease in native woman. Hemoglobin, 13.9 Gm.; red cells, 3.3 million. Cells enlarged, anisocytosis increased, very good correspondence.

Fig. 42.—Pernicious anemia. Hemoglobin, 11.2 Gm.; red cells, 3.2 million. Cells very large, anisocytosis increased, marked nervous symptoms. Cells rather large, anisocytosis

spandence.

Fig. 43.—Pernicious anemia. Hemoglobin, 13.1 Gm.; red cells, 3.1 million. Mean diameter, normal, anisocytosis increased, rather more pronounced with diffraction

method. Hemoglobin, 8.5 Gm.; red cells, 3.1 million.

Fig. 44.—Pernicious anemia. Hemoglobin, 10.9 Gm.; red cells, 3.2 million. Cells enlarged, anisocytosis increased, good correspondence.

Fig. 45.—Pernicious anemia. Hemoglobin, 8.0 Gm.; red cells, 2.7 million. Cells enlarged, but striking feature was very much increased

Fig. 46.—Pernicious anemia. Hemoglobin, 10.2 Gm.; red cells, 3.5 million. Mean diameter normal, anisocytosis much

ment; then come the cells of mean diameter and, last, the smallest cells. Another important feature is that the diffraction method is sensitive enough to show definite improvement in a week or less when proper treatment is instituted and may therefore take the place of the more complicated counting of reticulocytes.

The case marked F.A.J. 1 suffered from familial acholuric jaundice and was examined twice, the first time for diagnostic purposes, and then again a fortnight after splenectomy. Here, too, the improvement is brought out very clearly by the diffraction method.

Figs. 49 and 50.—Illustrate the results of diffraction measurements in the follow-up of patients.

SUMMARY

A historical introduction shows how blood films came to be used as diffraction gratings for the measurement of red cells, and how the technique was further developed, resulting in Pijper's Blood Cell Tester. This is a very simple apparatus which can easily be constructed from simple materials. Its leading feature is that it permits the direct comparison on one and the same screen of the diffraction spectra produced by two different blood films. Since the diffraction spectra are the expression of the red cell diameters, it follows that one can directly compare the cell diameters of standard normal blood with those of a patient, or of two blood films from the same patient, taken at different times. This arrangement on occasion does away with the necessity for actual measurement; a glance at the screen may be sufficient to decide what sort of anemia one is dealing with or whether the patient is making progress. Improvement in cell diameters after a few days of treatment can readily be observed by direct comparison of two blood films in the apparatus.

The advantages of this "duplication" technique and apparatus are compared with the various instruments suggested by other authors, which, although based on the same original idea, do not always do full justice to the possibilities of the diffraction method.

The main purpose of the paper is to show that with the diffraction method in the form finally developed, it is possible not only to determine the mean diameter, but also the degree and quality of anisocytosis present in a blood film. These determinations do not take more than a few minutes, which means a great saving in time as compared with the making of a Price-Jones curve. This diffraction method gives, in a fraction of the time, practically the same information as the laborious microscopic measurements of Price-Jones. It also takes into account a much larger number of cells. Its speed makes it readily applicable to any patient.

For differential diagnosis the importance of determining red cell diameters is admittedly great. The diffraction method in its proper form as described herein does this directly and very reliably. The indirect methods aiming at similar information by determining hemoglobin index or mean cell volume cannot be as reliable because it is necessary to divide two doubtful values through one another, and this may lead to gross distortion of actual conditions, as shown in this paper. Also, these indirect methods give mean values only, not degree and quality of anisocytosis.

The opportunity is taken of pointing out that blood films must be made with adequate skill and care to be of use in diffraction measurements. It seems that disappointments with the diffraction method in many instances are due to indifference in this respect.

In this paper are discussed the theoretical foundations of the diffraction method, and the technique of making accurate measurements is given in detail. A conversion table (Table III) is included which translates the diameters of the colored rings into microns, both for mean diameter and degree and quality of anisocytosis. This table is suitable for any apparatus working with a lens of 20 cm. focal distance.

A series of cases is described in which both microscopic measurements and complete diffraction measurements were performed, the identical blood films being used for both methods. It is seen that the results correspond quite well.

Finally, the usefulness of the diffraction method for following cases under treatment is illustrated.

PRACTICAL INSTRUCTIONS FOR BUILDING A DIFFRACTION APPARATUS

A suitable apparatus embodying the principles of Fig. 2 can easily be built, following the lines of the Pijper's Blood Cell Tester, of which an illustration is given in Todd and Sanford¹⁰ and in other textbooks. One needs a wooden box, at the bottom of which is placed a small electric lamp, providing a narrow light source. A small circular diaphragm on top of the lamp produces a parallel beam of light, which reaches the horizontal stage of the apparatus, in which there are two small holes. (It would be a refinement to use a collector lens to provide a parallel beam.) In the Zeiss apparatus, contrary to the diagram, the beam strikes a simple lens, underneath the stage, before it reaches the blood films on the stage. This is the only lens which is essential. It is a simple lens of 20 cm. focal distance, cost about \$1.00.

5 diopters is good enough. The horizontal stage enables one to move the blood films until the best spot is found. The vertical partition which separates the two diffraction patterns should be made of a thin piece of metal. The receiving screen forming the top of the apparatus should be of fine grain ground glass; various kinds should be tried to get best results.

I wish to thank two of my technical assistants, Mrs. J. van Sighem and Miss J. Todd, for great care and patience exercised in the making of Price-Jones curves.

THE ROLE OF PHAGOCYTOSIS IN RESISTANCE, AS RELATED TO AGE OF GRANULOCYTES FOLLOWING PRIMARY AND REINFECTION STUDIES WITH HEMOLYTIC STREPTOCOCCI IN MACACUS RHEUS

SAMUEL SASLAW, PH.D., M.D., AND CHARLES A. DOAN, M.D.
COLUMBUS, OHIO

IN THE studies previously reported from this laboratory¹⁻³ which attempted to analyze the relative roles of cellular and humoral immune factors in monkeys subjected to respiratory infections with the hemolytic streptococcus, Group C, not only the quantitative response of the neutrophilic granulocytes, but also the phagocytic activity (opsonocytophagic index of Huddleson⁴) in terms of relative cell maturity were investigated. To an initial intranasal infection with the streptococcus, there was invariably an immediate response marked by an effective granulocytic leucocytosis. A later reinfection with the same organism quite as regularly failed to elicit any appreciable disturbance in the quantitative equilibrium of the circulating white blood cells. Yet there was no apparent change in the effective resistance of the animals. It seemed desirable, therefore, to analyze the opsonic index under these two conditions, and at the same time to correlate the Arneth-Schilling index of maturity of the granulocytes to determine the optimum age for maximum phagocytic function under the conditions of this experimental study.

Previous studies by various workers concerning the qualitative and quantitative responses of the neutrophilic leucocytes to infection are not in agreement. Much of the discrepancy may be attributed to differences in technique and in the materials employed. Hamilton-Black⁵ in 1913 observed the polymorphonuclear leucocytes during the tuberculin treatment of tuberculosis. After tuberculin he noted an increase in the number of mature cells as well as a total increase in leucocytes. Of the number of tubercle bacilli ingested (method not described) he found that neutrophils with one nucleus engulfed 10 per cent; with two nuclei, 18 per cent; with three nuclei, 22 per cent; and with four and five nuclei, 25 per cent, respectively. Arneth⁶ in 1920, in examining purulent exudates but no peripheral blood preparations, reported that only mature leucocytes (Class 2 or 3) were concerned in phagocytosis, that the very young and the senile cells did not participate. Ponder and Flinn⁷ in 1926 found no difference in the phagocytic properties of cells using *Mycobacterium tuberculosis*, *Escherichia coli*, *Staphylococcus aureus*, and *Neisseria catarrhalis*. Jacobsthal⁸ in 1921 used citrated preparations from acute myeloblastic leucemia, myeloid leucemia, and Hodgkin's disease with multiple skin infiltrations and high eosinophilia. After

Received for publication, April 28, 1947.

finding staphylococci and the anthrax bacillus unsatisfactory, he used cinnabar and *Micrococcus tetragenus*. He concluded that:

1. Neutrophilic myeloblasts and myelocytes have the ability, in vitro, to phagocytize cinnabar and bacteria.

2. Eosinophiles are phagocytic.

3. Observations on the blood of two cases of leucemia showed that adult granulocytes but not myelocytes were able to phagocytize bacteria and foreign erythrocytes.

4. Eosinophiles in cases of Hodgkin's disease readily phagocytized staphylococci, micrococci, and tubercle bacilli.

Jung¹¹ in 1932 noted that as the number of cells increases, the percentage of phagocytes diminishes.

EXPERIMENTAL

Materials and Methods.—Daily determinations based on a modification of Huddleson's method⁶ were made in selected monkeys in order to study any variation in the phagocytic properties of the circulating granulocytes of the infected animals. Young cultures of *Streptococcus hemolyticus*, Group C, which were culturally characteristic and not resistant to phagocytosis, were employed. For each opsonic determination, cultures grown on North's chocolate gelatin agar slants for eighteen to twenty-four hours at 37° C. were used. By means of a sterile wire loop the growth was gently removed from the surface and emulsified in sterile 2 per cent sodium citrate in physiologic saline solution which served both as a diluent and anticoagulant. The suspension was then adjusted by means of a nephelometer to a standard turbidity approximately equivalent to 30 billion bacteria per milliliter. After allowing a few minutes for any clumps or particles to settle, 0.1 ml. of the suspension was introduced into sterile agglutination tubes to which an equal amount of blood freshly obtained from the marginal ear vein was added. After being well shaken, the tubes were placed in a water bath adjusted to 37° C. The tubes remained in the bath approximately one hour when they were shaken again and then incubated an additional hour at 37° C. Duplicate thick smears of the incubated blood-bacterial suspension were made on clean glass microscopic slides and dried rapidly by means of an electric fan. The slides were then placed in a 5 per cent formalin and 1 per cent acetic acid solution for four minutes in order to dissolve the red corpuscles and to fix the leucocytes, following which the slides were dried with bibulous paper and the smears stained for thirty seconds with Bordet-Gengou's toluidine blue. In determining the degree of phagocytosis, the bacteria in twenty-five polymorphonuclear cells were counted and the phagocytic power measured by the average number of bacteria engulfed by each phagocyte in contrast with the number phagocytized in the presence of blood taken previous to inoculation. So far as possible, the individual cocci were counted. Daily blood counts were made on each animal over a period of two to three weeks. The age of each granulocyte in terms of lobation of the nucleus was recorded, and the engulfed bacteria counted.

Experiment I.—As noted in earlier studies¹⁻⁵ primary intranasal inoculation with the Group C streptococcus was followed by a sharp polymorphonuclear leucocytosis but the phagocytic index was not appreciably altered. Reinnoculation, however, was followed by a sharp increase in individual phagocytosis but no leucocytosis occurred. Thus, in order to evaluate quantitatively the number of bacteria phagocytized daily, the total number of bacteria engulfed was determined by multiplying the opsonic index by the total number of neutrophils. The results obtained in the two monkeys to be discussed are representative of those obtained in a group of twenty-three animals studied.

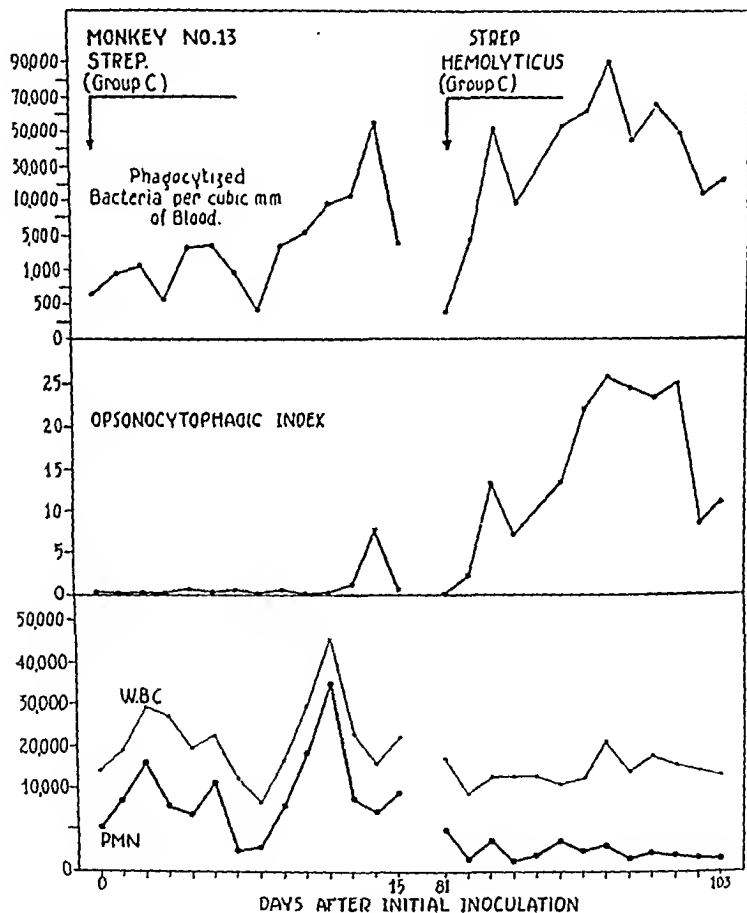

Fig. 1.

As noted in Fig. 1, Monkey 13 showed a marked polymorphonuclear leucocytosis after primary inoculation with relatively little increase in the opsonic index. However, there was a definite increase in the total number of bacteria engulfed from a preinoculation level of 672 bacteria per cubic millimeter of blood to a maximum of 55,600 bacteria on the twelfth postinoculation day, with intermediate levels varying from 456 to 13,338 bacteria per cubic millimeter. At

the time of maximum phagocytosis, the opsonic index was 8 as compared with 0.2 at the time of inoculation, while the neutrophils totaled 7,000 as compared with 4,000. On the tenth postinoculation day the total number of bacteria engulfed was 9,660 per cubic millimeter despite a low opsonic index of 0.3 due to the neutrophilic increase (34,500 polymorphonuclears); on the eleventh day there were 13,338 bacteria phagocytized per cubic millimeter when the opsonic index was only 1.5, but the neutrophils totaled 8,775.

FIG. 2.

Following reinoculation, three months after primary infection, there was a consistently higher number of bacteria engulfed due primarily to the increase in individual cell phagocytosis without leucocytosis, with the highest number of bacteria engulfed being 87,000 on the seventh day after reinoculation with the streptococcus, at which time the opsonic index was 28 while total neutrophils were only 3,310. Twenty-four hours after reinoculation with the streptococcus:

the opsonic index was 2.5 and the average number of bacteria phagocytized per cubic millimeter was 50,274; then it fell to 9,855 after forty-eight hours but increased on the third day to 50,557. For the next week the average number of bacteria phagocytized per cubic millimeter varied between 45,000 and 87,000, with opsonic indices ranging between 13.5 and 25.

Thus, although it was apparent that there was increased phagocytosis per individual cell following reinoculation as compared with primary inoculation with the streptococcus, due to the greater leucocytosis following primary inoculation there was actually less difference in the degree of total phagocytosis than would be expected from evaluation of the opsonic index alone.

Similarly, as noted in Fig. 2, there was a low opsonic index with a compensatory leucocytosis following primary instillation of the streptococcus, as compared with a lack of leucocytosis but with increased individual cell phagocytosis after reinoculation. Monkey 12 is also representative of the animals showing this response. The preinoculation opsonic index of 0 in this animal showed a slight increase to only 0.3 on the fifth day after primary inoculation with the streptococcus, with resultant indices for the next three weeks varying between 0 and 0.9. However, due to the leucocytosis there was an increase in total numbers of bacteria engulfed per cubic millimeter to as high as 17,700 on the twelfth day (opsonic index, 0.8; neutrophils, 22,137), with the average number of bacteria engulfed per cubic millimeter being about 4,000. Before reinoculation with the streptococcus three months later, the opsonic index was 0.6; neutrophils, 5,030; and the total number of bacteria engulfed per cubic millimeter, 3,018. Within twenty-four hours the opsonic index rose to 6.1, with 33,600 bacteria engulfed per cubic millimeter, although there was no increase in neutrophils (5,510). For the next two weeks the opsonic index averaged between 6 and 18, except for one low value of 1.8 on the third day. The total number of bacteria engulfed per cubic millimeter rose to 83,600.

Here again there was a greater degree of phagocytosis per individual cell following reinoculation with the streptococcus than after primary inoculation. A greater total bacterial phagocytosis, however, followed this primary inoculation than might have been expected from the very low opsonic index.

Experiment II.—The monkeys used in this study were animals which had been infected by intranasal inoculation with the Group C hemolytic streptococcus three to six months earlier. After reinfection the granulocytes in these animals exhibited a marked increase in phagocytic activity which had not been apparent after primary infection, without the significant initial quantitative leucocytosis.

Fig. 3 presents graphically the relative degree of phagocytic activity by the various age groups of polymorphonuclear leucocytes. Monkey 8, for example, showed a progressive phagocytic efficiency beginning with the band forms (seventeen bacteria per cell), reaching a peak of twenty-two organisms per cell in the three-lobed neutrophils, and then showing a gradually diminishing effectiveness in the four-, five-, and six-lobed cells which handled twelve, three, and six bacteria, respectively. Monkey 6 showed a similar picture with ten, thirteen,

and eleven bacteria engulfed by the one-, two-, and three-lobed cells, respectively, while the four-, five-, six-, and seven-lobed neutrophils each engulfed from four to seven bacteria.

The young cells in Monkey 13 likewise showed greatest phagocytic activity by the one-, two-, and three-lobed cells, while Monkey 17 showed a gradual progressive decrease in phagocytosis inversely proportional to the age of the leucocytes. The band cells in Monkeys 16, 29, and 30 had the highest phagocytic index with gradual diminution in phagocytosis as cell age increased.

In contrast, there apparently was no correlation between cell maturity and phagocytosis following primary infection. The small degree of phagocytosis observed here was apparently distributed at random among the various cells.

Fig. 3.

DISCUSSION AND SUMMARY

Earlier studies¹ from this laboratory have shown that monkeys receiving intranasal inoculations of *Streptococcus haemolyticus*, Group C, reacted with an immediate marked and clear-cut peripheral leucocytosis but without any elevation in the opsonic index as measured by *in vitro* tests. Reinoculation with the same agents three to six months later resulted in no appreciable leucocytosis, but there was a prompt and significant increase in phagocytosis by the individual granulocytes. If the *in vitro* determinations of the potential phagocytic capacities of the neutrophilic granulocytes for hemolytic streptococci multiplied

by their number per cubic millimeter in the circulating blood may be interpreted as a relative index of the cellular component of resistance to infection with these organisms, then the inverse ratio of these two phenomena, which occur in primary versus reinfection states, becomes not only interesting, but deeply significant as well. On the basis of the findings here presented, we agree with Jung,¹¹ that the lower the phagocytic index, the greater the number of granulocytes required to control any given infection. The absolute leucocytosis following close upon a primary infection with low opsonic index would seem to represent a compensatory response in which the resistance of the host or his cellular protection is measured by the sheer numbers of available phagocytes. When the relatively low opsonic indices are evaluated in relation to the total available polymorphonuclear leucocytes, the absolute number of bacteria phagocytized by the neutrophils will be greater than is at first evident from a cursory examination of the opsonic index alone. On the other hand, after reinoculation with the streptococci in these studies, there was a compensatory qualitative change in the phagocytic activity of the granulocytes without an absolute quantitative elevation in their number. In this group a qualitative cellular-humoral response apparently served as a compensatory protective mechanism by which fewer cells, each with greater individual phagocytic capacity, were able to control the infection effectively. Combining both the quantitative (leucocytic) and qualitative (phagocytic) responses, a greater total bacterial phagocytosis was noted following reinoculation with the streptococcus, but the difference with this cellular-humoral response was not as great as would be expected from evaluation of the opsonic index alone.

Wood¹² has recently called attention to the importance of phagocytosis of bacteria by neutrophilic granulocytes in bacterial pneumonia in the absence of demonstrable specific opsonins or antibodies. The motility of the cells in and through the fixed tissues brings direct contact with the invading organisms resulting in ready cytoplasmic inclusion. Our observations strongly suggest the acquisition of a highly specific humoral catalyst, which, upon reinoculation of the same pathogenic agent some months after recovery from the first invasion, greatly facilitates this phenomenon of spontaneous cellular phagocytosis, so that far fewer polymorphonuclears are needed to combat reinfection effectively the second time than the first.

The younger mature cells, according to the Arneith-Shilling index, were definitely more effective in their phagocytic activities in this study, with a decrease in phagocytic capacity as the individual cell age increased. These observations suggest that quantitative phagocytosis bears a direct relationship to the age and motility of the neutrophils. In the presence of opsonins, the more actively motile "left-shifted" cells have shown the greatest avidity in engulfing reinfecting pathogenic bacteria.

OUTBREAK OF DIARRHEAL DISEASE ASSOCIATED WITH PARACOLON

HERBERT F. R. PLASS, M.D.
MINNEAPOLIS, MINN.

ORGANISMS of the incompletely circumscribed paracolon group are felt to be in a controversial position regarding their pathogenicity. A few outbreaks of diarrheal disease in human beings and in animals associated with paracolon flora in the intestinal tract have been recorded,¹⁻³ although usually it has been impossible to fulfill the postulates of Koch. Similarly, this report concerns an outbreak of diarrhea during which an organism of the paracolon group was isolated from the food consumed and from the stools of thirteen of the sixteen patients who required hospitalization.

In an Army officers' mess, fricasseed chicken was served to about 250 diners from 5:30 to 7:30 P.M. The chicken had been cooked in several large vessels and served directly from them. Approximately 100 servings were made from the one container of chicken which was found to contain paracolon bacteria when cultured later. There were eighty known cases of diarrhea; it could not be determined whether all these cases originated from the same batch of chicken. However, all patients had eaten chicken, and one had eaten nothing whatever except chicken.

About two hours after eating, the first patient became nauseated, had abdominal cramps, and soon began to vomit and pass watery stools. Other cases appeared between three and twelve hours after eating; the largest number of cases occurred four hours after eating the chicken. The five most severely affected patients developed mild shock which was relieved by simple measures. A total of eighty patients reported for treatment; how many were treated elsewhere could not be determined. Sixteen patients required hospitalization; these were the only ones available for culture during the acute illness. After twenty-four hours, all sixteen patients were symptom free except for weakness and had been discharged from the hospital. No sulfonamide therapy was given.

A rectal swab made from each hospital patient about nine o'clock in the morning after onset of the illness was planted on *Salmonella-Shigella* agar, on eosin-methylene blue agar, MacConkey's medium, and desoxycholate citrate agar and then placed in nutrient broth. Four hours later the nutrient broth was subcultured to eosin-methylene blue agar. No staphylococci were recovered from any of the cultures. In about eight hours, some *Salmonella-Shigella* agar plates showed heavy growth of lactose-nonfermenters. Almost all plates showed heavy growth of lactose-nonfermenters after twenty-four hours. Colonies were picked at twenty-four and forty-eight hours and, after replating, biochemical characteristics of the isolates were determined. Sugar fermentations in bromocresol purple-nutrient broth were read daily for fourteen days. Indole forma-

tion was determined in tryptone water with Kovac's reagent after twenty-four hours of incubation. Citrate utilization was determined on Simmons' medium after twenty-four hours. Motility tests were done in 0.3 per cent agar and were read after five days of incubation at room temperature. Methyl red and Voges-Proskauer tests were done with the M.R.-V.P.* medium. Gelatin liquefaction was read by refrigerating five-day cultures. The urease test of Rustigian and Stuart⁹ was used.

The organism recovered from thirteen of the sixteen patients resembled paracolon 29911 of Stuart and co-workers¹⁰ (Table I). It also bears a superficial resemblance to the genus *Proteus*, although it does not attack urca. It produces a bubble of gas in dextrose broth (which is not revealed after five days' incubation of a double sugar agar slant). Sucrose and mannitol are fermented in two to six days. Lactose, salicin, xylose, maltose, and rhamnose are not attacked in fourteen days. Methyl red and Voges-Proskauer reactions are negative, indole is produced, sodium citrate is utilized, urease is not formed, and the organisms are motile.

TABLE I

	DEXTROSE	LACTOSE	SUCROSE	SALICIN	MALTOSE	MANNITOL	INDOLE	V.P.	CITRATE	UREA	MOTILITY
29911-like strain	AB	-	A ₆	-	-	A ₂	+	-	+	-	++
29911 (Stuart)	AB	-	A ₆₋₂₀	-	-	-	+	-	+	- + w	++
<i>P. rettgeri</i>	AB	-	AG ₄	-	-	AG	+	-	+	+	++
<i>P. morganii</i>	AG	-	-	-	-	-	+	-	-	+ s	++
<i>P. vulgaris</i>	AG	-	AG	-AG	AG	-	+	-	+	+	++
<i>P. mirabilis</i>	AG	-	AG	-	-	-	-	±	+	+	++

AB, acid and a bubble of gas; A₆, production of acid in six days of incubation; AG, acid and gas; -AG, some strains produce acid and gas, others do not; +, positive test or reaction; - + w, some strains negative, some weakly positive; + s, slow reaction; -, no reaction or negative test.

This organism differs from the one described by Stuart¹⁰ as 29911 in that sucrose is fermented more rapidly (seven as against twenty days) and mannitol rather than maltose is attacked.

Two of the five strains isolated from the plates prepared from leftover chicken showed properties similar to this typical organism except that one produced a bubble of gas in sucrose broth in thirty days and the other was slow in developing motility.

Nineteen of the cultures from this outbreak (more than one isolate from some patients) have been found to be antigenically identical or very closely related. Further study of these cultures by Stuart has confirmed both biochemical and serologic connections with Type 29911 paracolon (Stuart). These strains may be classified as an atypical 29911 paracolon for the present.¹¹

Rapid survey of the other strains isolated shows many related cultures and a large number not so apparently related. In addition to the paracolon described, *Proteus rettgeri* or *Proteus mirabilis* were isolated from twelve of the

*Difco Laboratories, Inc., Detroit, Mich.

sixteen cases. *Proteus mirabilis*, together with the paracolon, was found in the chicken. Moreover, a large number of urease-negative organisms were recovered which differed in one or more respects from the 29911-like paracolon which was most prevalent.

COMMENT

Careful application of standard methods to the study of an outbreak of common diarrheal disease revealed a paracolon as the predominating organism in the food implicated and in the stool cultures of the hospitalized patients. It appears unlikely that a recognized pathogen may have been overlooked. Whether the paracolon or the various *Proteus* species or the combination of them caused the outbreak cannot be definitely decided. A common pathogen occurring in the same circumstances would have been considered the etiologic agent. *Proteus rettgeri* and the 29911-like paracolon occurred together in several patients; it is noteworthy that the only important difference between the two is the ability of the former and the inability of the latter to attack urea. One is led to speculate as to their relationship, when they are associated in such a violent diarrhea.

THE EFFECT OF THE RATE OF ADMINISTRATION OF AMINO ACID PREPARATIONS AND BLOOD AMINO ACID NITROGEN LEVEL ON THE PRODUCTION OF NAUSEA AND VOMITING

CHARLEY J. SMYTH, M.D., ANDREW G. LASICHAK, M.D.,
AND STANLEY LEVEY, Ph.D.
ELOISE, MICH.

THE intravenous administration of protein hydrolysates in the management of various protein deficiency states is now widely accepted. During the infusion untoward reactions occasionally occur which make it necessary to interrupt this form of supplementary protein therapy. These reactions include either one or any combination of the following signs or symptoms: Anorexia, nausea, vomiting, flushing, formication, headache, and dizziness.

It has been reported previously that under certain conditions the intravenous administration of casein digests produced a depressing influence on voluntary food intake.¹ In that study no direct relationship was found between the rate of administration and the degree of anorexia. Elimination of the other undesirable side effects could usually be accomplished by reducing the rate of the infusion. Clinically it is not desirable to subject a patient to prolonged infusion requiring three to four hours if it is possible to increase the rate of administrations without ill effects. For example, in order to give large amounts of these preparations by the intravenous route the patient will be required to remain inactive with one arm extended for long periods of time. The possibility of infection occurring at the site of the injection is greatly enhanced by the slow administration of these preparations.

In this hospital three different patients are known to have developed abscesses at the site of infusion, and five others showed clinical evidence of cellulitis following the slow rate of administration of a casein digest.

Hoffman, Kozoll, and Osgood² observed that nausea and vomiting occurred in patients who received a casein hydrolysate administered at rapid rates. These investigators are of the opinion that if the plasma amino acid nitrogen level exceeded 10 mg. per cent, nausea and vomiting usually occurred. During the course of previous studies¹ it was shown that a mixture of pure amino acids could be administered at exceedingly rapid rates without causing any undesirable effects.

The present investigations were undertaken to determine whether the relationship of the amino acid nitrogen content of the blood to nausea and vomiting, as proposed by Hoffman, Kozoll, and Osgood, existed with other amino acid preparations. In addition, the effect of the rate of administration on the production of these ill effects was studied.

From the Departments of Medicine and Physiological Chemistry, Wayne University College of Medicine, Detroit, Mich., and The Wayne County General Hospital, Eloise, Mich.

A preliminary report of this investigation appeared in the proceedings of the Detroit Physiological Society published in *J. Michigan M. Soc.* 46: 332, 1947.

Received for publication, April 21, 1947.

METHODS

The patients used in this study were convalescent hospital subjects who had no known metabolic disorders. The intravenous injections were given as though they were a part of their regular therapy; thus the psychologic factors were minimized. The amino acid preparations were administered intravenously at rates varying from 5 to 100 ml. per minute, and if nausea or vomiting occurred a blood sample was immediately withdrawn from the opposite arm for amino acid nitrogen determination. In those patients in whom no symptoms occurred, a blood sample for amino acid content was taken just before the end of the infusion.

Five different amino acid preparations were used in this study. Preparation I* was an enzymatic hydrolysate of casein which was administered as a 10 per cent solution. Preparations II† and IV‡ were acid digests of casein; the former was a 15 per cent solution and the latter a 6 per cent solution. Tryptophane was added to both Preparations II and IV, and, in addition, methionine was added to Preparation IV. Preparation III‡ consisted of a mixture of the ten "essential" amino acids plus the amino acid glycine. Approximately 50 per cent of the amino acids in this mixture were in the racemic form. Preparation V‡ was a vuj-n-type³ mixture of amino acids prepared by the recombination and fortification of fractions of an acid hydrolysate of casein. It was administered as a 10 per cent solution. Of the total nitrogen in this mixture approximately 50 per cent was derived from essential amino acids.

Since the relationship between the amino acid nitrogen level of the blood and the presence of nausea and vomiting was one of the major interests of this study, no attempt was made to adjust the nitrogen concentrations of the preparations used. The volume of solution infused was the contents of either a 500 or a 1,000 ml. bottle. In the instance of Preparation II, however, due to the hypertonicity of the 15 per cent solution, 266 ml. of the protein hydrolysate were diluted to 500 ml. with sterile water and the resulting mixture administered.

The determination of the amino acid nitrogen content of the blood was made by the copper method of Albanese, and Irby,⁴ all values being expressed as milligrams of amino acid nitrogen per 100 ml. of plasma.

RESULTS

The influence of the rate of intravenous infusion on the occurrence of nausea and vomiting for all these preparations is summarized in Fig. 1. This factor was studied in 115 subjects. The casein digests (Preparations I, II, and IV) all had a high content of glutamic and aspartic acids, whereas the amino acid mixtures (preparations V and III) contained, respectively, little or none of these dicarboxylic acids. There appeared to be a slight increase in the incidence of nausea or vomiting when the rate of administration of preparation

*Preparation I (Amlgen, 10 per cent solution) was supplied by Mead Johnson and Company, Evansville, Ind.

†Preparations II (Parenamine) and IV (6 per cent Parenamine) were furnished by the Frederick Stearns & Company, Detroit, Mich.

‡Preparations III (Vuj) and V (Vuj-n-IX) were provided by Merck & Company, Inc., Rahway, N. J.

I was increased from 5 to 15 ml. per minute. In the case of Preparation II or IV, the increased rate of administration was usually accompanied by a marked increase in the incidence of nausea or vomiting. On the other hand, the administration of the amino acid mixtures, Preparation III or V, was accompanied by an exceedingly low incidence of ill effects. In this connection it is noteworthy that Preparation III has never made any patient ill, either in this or in earlier studies carried out in this hospital. The incidence of undesired side reactions was slightly higher when Preparation V was administered. It should be emphasized that the amino acid mixtures, Preparations III and V, were administered at increasing rates which began at the highest tolerated level for the protein hydrolysates. In many cases Preparation III was given at the rate of 500 ml. in eleven to thirteen minutes, whereas Preparation V was administered at the unusually rapid rate of 100 ml. per minute; thus, a 500 ml. bottle of this amino acid mixture was given in five minutes. In some of these cases flushing and formication occurred, but there was no nausea or vomiting.

Fig. 1.—Influence of rate of administration on incidence of nausea or vomiting (115 subjects). The numbers in the squares at the top of each column indicate the number of subjects who received one of the five preparations shown along the bottom of the chart.

The relationship between the occurrence of vomiting and the level of the amino acid nitrogen in the blood plasma is summarized in Fig. 2. In this part of the study an attempt was made to vary the amino acid levels of the blood by varying the rate of the intravenous infusion. The administration of Preparation I caused no significant change in the incidence of nausea and vomiting until the amino acid nitrogen content of the plasma reached 13 mg. per 100 ml. or greater, at which levels 50 per cent of the patients became ill. With levels

below this, the frequency of nausea and vomiting ranged from 25 to 30 per cent of the patients studied. The highest amino acid nitrogen level in the plasma attained with this Preparation was 34 mg. per cent and in this subject only nausea occurred. When Preparation II was used, the incidence of nausea and vomiting increased progressively with an increase in the plasma amino acid nitrogen; if the amino acid nitrogen level of the plasma reached 9 mg. per cent or greater, all the subjects either became nauseated or vomited. With Preparation III there was no nausea or vomiting in any of the seven subjects reported in this study. In another series of fifteen patients who received forty-six infusions using this preparation, there also was no occurrence of any ill

Fig. 2.—
acid nitrogen
bottom of the
attained in the group of subjects directly above.

or vomiting in relation to preparations and blood amino
The small numbers (from 1 to 15 or greater) along the
range of blood amino acid nitrogen level in mg. per cent

effect. In a qualitative manner, Preparation IV reacted similarly to Preparation II, though the incidence of nausea and vomiting was not as great. Preparation V was administered at exceedingly rapid rates, and even at the highest plasma amino acid nitrogen level obtained, the incidence of nausea and vomiting was only 20 per cent. An amino acid nitrogen value of 44 mg. per cent was reached in one patient receiving Preparation V with no ill effects whatsoever.

DISCUSSION

From the data presented in this investigation the incidence of nausea and vomiting appears to depend on the amino acid composition of the preparation used rather than on the average rate of administration or on the plasma amino acid nitrogen level. In all patients who received casein hydrolysates (Preparations I, II, and IV) the incidence of nausea or vomiting was greater than in those subjects who received the amino acid mixtures (Preparations III and V). In the case of Preparation II it was found that the presence of an amino acid nitrogen content in the plasma of about 10 mg. per cent or greater was usually associated with the occurrence of nausea or vomiting. This observation is in agreement with the work of Hoffman, Kozoll, and Osgood,² who used the same preparation.

The possibility that glutamic and aspartic acids are responsible for these toxic symptoms has been studied in both dogs and human subjects,⁵⁻⁸ Preparation III was completely devoid of glutamic and aspartic acids and its use parenterally did not produce either nausea or vomiting. Preparations I, II, and IV are produced by hydrolyzing casein, a substance having a high content of these dicarboxylic acids, and therefore these digests are considered to have a large content of glutamic and aspartic acids. The glutamic acid content of Preparation V is 1.25 Gm. per liter or less.* Thus the dicarboxylic acid content of this preparation is considerably lower than in mixtures resulting from the direct hydrolysis of casein. One explanation for the occurrence of nausea and vomiting resulting from the intravenously administered casein digests is that the blood dicarboxylic acid concentration becomes high enough to exceed a nausea threshold. The amino acid Preparations III and V, on the other hand, allow high blood amino acid nitrogen levels to be attained without nausea simply because little or no dicarboxylic acid is being added to the blood stream. Casein digests also differ from the amino acid mixtures by their content of nonamino acid substances which may be an additional factor contributing to the production of these ill effects. The possibility of a correlation between the plasma glutamic acid content and the presence of nausea and vomiting is being investigated.

Any evaluation of the toxic manifestations produced by the parenteral administration of amino acid preparations is difficult because the responses vary widely among apparently normal individuals.

SUMMARY

The effect of five different amino acid preparations on the production of nausea and vomiting was investigated in human subjects. In all patients who received casein hydrolysates intravenously, the incidence of nausea or vomiting was greater than in those subjects who received the amino acid mixtures. Mixtures of amino acids can be administered intravenously at high rates without producing these effects. The casein hydrolysates, on the other hand, must be administered at considerably slower rates to avoid nausea and vomiting.

*Personal communication from Dr. E. E. Howe, Merck & Company, Inc., Rahway, N. J.

With the mixtures of amino acids there appears to be no plasma amino acid nitrogen level at which nausea and vomiting uniformly occur. With casein digests, increased incidence of these ill effects is usually associated with high amino acid nitrogen values. The role of the dicarboxylic acid in the production of nausea and vomiting is discussed.

The production of nausea and vomiting by the intravenous administration of amino acid preparations depends on the preparation used and individual tolerance rather than on the degree of hyperaminoacidemia.

The authors wish to acknowledge the technical assistance of Dorothy L. DeZelia in this study.

STUDY OF A NEW SEDATIVE-HYPNOTIC DRUG (3,3-DIETHYL-2,4-DIOXOTETRAHYDOPYRIDINE)

S. CHARLES FREED, M.D.
SAN FRANCISCO, CALIF.

WHILE there is an abundance of sedatives and hypnotics available to physicians, none is completely satisfactory. In fact, even those which are most popular with the profession occasionally elicit untoward side reactions such as drowsiness, "hangover," excitation, and delirium, as well as allergic responses involving chiefly the skin. Such toxic effects are especially encountered with the barbiturates. Thus, there is a place for a mild hypnotic preparation which is distinguished by a minimum of side-reactions and which chemically does not belong to the barbiturates.

In the light of the foregoing it was decided to undertake the clinical appraisal of a sedative-hypnotic compound (3,3-diethyl-2,4-dioxotetrahydropyridine) which appeared to afford certain advantages over the barbiturates, as substantiated by findings of Koppányi, Herwick, Linegar, and Foster.* These investigators explored the pharmacology of the drug extensively, and some of their observations are summarized here.

The minimal lethal dose of the aforementioned pyridine compound for rabbits was 500 to 650 mg. per kilogram orally and 300 to 350 mg. per kilogram intravenously. In aqueous solution the drug was readily absorbed following oral, intramuscular, subcutaneous, and intraperitoneal administration. The smallest oral dose required in the rabbit for motor paralysis and sensory depression was 250 mg. per kilogram. Sleep was induced within ten minutes when 150 mg. per kilogram were given intramuscularly or intraperitoneally to rabbits, but by the subcutaneous route this dose produced only drowsiness. Motor incoordination, the first sign of effect of the drug, occurred usually within one or two minutes following intramuscular or intraperitoneal injection. In two rabbits receiving daily 250 mg. per kilogram parenterally for seven days, there was no evidence of accumulation. The animals eliminated at least five-sixths of the dose within twenty-four hours. With regard to the duration of action, it was shown that rabbits eliminated, during an average period of five and one-third hours, about 70 per cent of the intravenous fatal dose; that is, about 13 per cent per hour. The average sleeping time from approximately 60 per cent of the minimal lethal dose was found to be as follows: eight hours (rabbits, orally), three and one-half hours (rabbits, intravenously), and five hours (dogs, intravenously). There was great individual variation in recovery time but no evidence of acquired tolerance.

Received for publication, April 26, 1917.

TABLE I

RABBITS ON INTRAVENOUS ADMINISTRATION	3,3-DIETHYL-2,4-DIOXOTETRAHYDRO-PYRIDINE	BARBITAL
Narcotic dose for 50% of animals (ND50) in mg./kg.		
Lethal dose for 50% of animals (LD50) in mg./kg.	86	140
	350	415

TABLE II

MICE ON SUBCUTANEOUS ADMINISTRATION	3,3-DIETHYL-2,4-DIOXOTETRAHYDRO-PYRIDINE	PHENOBARBITAL
Narcotic dose for 50% of animals (ND50) in mg./kg.		
Lethal dose for 50% of animals (LD50) in mg./kg.	200	222
	1,062	473

Tables I and II derived from data of the report by Koppányi and co-workers give some of the comparative results on the experimental pyridine compound, barbital, and phenobarbital.

From these figures it appears that intravenously in rabbits, the narcotic index (LD50/ND50*) of 3,3-diethyl-2,4-dioxotetrahydropyridine is 4.07 and that of barbital is 2.96. Similarly, on subcutaneous administration in mice the narcotic index of the experimental drug is 5.31, but that of phenobarbital is 2.13. It can be concluded that the margin of safety of the pyridine compound ranks decidedly higher than that of either barbital or phenobarbital.

Systemic reactions to 3,3-diethyl-2,4-dioxotetrahydropyridine were similar to those obtained with barbiturates; namely, a fall in blood pressure, depression of respiration and body temperature, and an increase in pulse rate. In a number of other animal experiments it was shown that the pyridine compound behaved typically of a true hypnotic by preventing convulsions from strychnine and picrotoxin. In dogs there was no appreciable effect on the blood sugar except after large amounts of the drug. Rabbits receiving twenty-five to eighty-six daily oral doses of from 15 to 400 mg. per kilogram of the pyridine derivative showed no deviations from normal in general appearance, food consumption, and reaction to other drugs. Likewise, there was no evidence of the development of tolerance, sensitization, or addiction in these animals, and changes in the blood picture were within normal limits.

With this pharmacologic evidence of effectiveness and low toxicity, clinical trials with 3,3-diethyl-2,4-dioxotetrahydropyridine† were instituted.

Obviously, the evaluation of therapeutic results with a sedative-hypnotic is open to a wide range of interpretation since the subjective response of patients to such medication depends upon many factors, some of which are beyond the

*LD50 is defined as the lethal dose for 50 per cent of the animals and ND50 as the narcotic dose which prevents a righting response in 50 per cent of the animals after the tails are pinched.

†3,3-diethyl-2,4-dioxotetrahydropyridine was furnished by Hoffmann-La Roche, Inc., Nutley, N. J., under the designation NU-903, through the courtesy of Dr. Leo A. Pirk.

control of the experimenter. Nevertheless, an attempt was made to evaluate the effects as objectively as possible. Thus relief from complaints was not suggested or promised to the patients, and the reports of responses to the drug were obtained as casually as possible. In fact, the patients were encouraged to volunteer their impressions. Furthermore, a relatively large number of subjects were tested so that many of the potential psychic factors which might influence the drug's appraisal could be neutralized.

NU-903 was administered to two groups of patients: one consisted of subjects suffering from insomnia, and the other of persons requiring daytime sedation because of nervous tension. Among the latter were patients with a variety of psychosomatic disorders.

In the first group there were ninety-six patients who had all complained that they slept poorly or fitfully. Of these, sixty-six received one tablet of NU-903 (0.2 Gm.) at bedtime; forty-two, including twelve who had failed to respond to the aforementioned dosage, were given two tablets (0.4 Gm.), all for at least seven consecutive nights. An uninterrupted period of trial makes changes more perceptible, and thus these patients were in a better position to appraise the effect of the drug on their sleep than if they had taken it only sporadically. The higher dosage was administered in those instances in which clinical appraisal indicated a more severe degree of insomnia or a more agitated mind.

The effects of this treatment are shown in Table III. The degree of the positive responses is indicated by the number of plus marks: three signs denote excellent; two signs, satisfactory; and one sign, fair results. Negative responses are designated by 0.

TABLE III. TREATMENT OF INSOMNIA WITH NU-903

DOSAGE	NUMBER OF PATIENTS	TOTAL NUMBER OF TREATMENT	AVERAGE ONSET OF EFFECT	AVERAGE DURATION OF SLEEP	RESULTS
0.2 Gm.	66	482	30 min.	6 hr.	10 +++
					21 ++
					24 +
					11 0
0.4 Gm.	42	478	30 min.	7 hr.	10 +++
					22 ++
					6 +
					4 0

It is apparent that 0.2 Gm. of NU-903 was not quite sufficient to induce satisfactory sleep in the majority of patients, although it did have a beneficial effect on many. It seems as though the desired therapeutic results were obtained with this dose only in persons who were sensitive to hypnotic drugs or whose insomnia was of a mild degree. Furthermore, it is evident that 0.4 Gm. of NU-903 produced excellent or satisfactory sleep in thirty-two of forty-two patients. (Among those reporting gratifying results on 0.4 Gm. were twelve patients in whom 0.2 Gm. had failed to induce satisfactory sleep.) Six patients claimed to have had only a fair degree of response with 0.4 grams. Finally, of the four subjects

who reported no results with this dose, three had previously experienced insufficient hypnotic effect from 0.1 Gm. of sodium pentobarbital, but they did have a good night's sleep from 0.2 Gm. of the latter somnifacient. From these results it may be concluded that 0.4 Gm. of NU-903 will produce a hypnotic effect comparable to that of 0.1 Gm. of sodium pentobarbital, the standard dose.

The onset of sleep, regardless of the dose, followed taking of the drug usually within thirty minutes, but never after more than sixty minutes. The duration of sleep averaged six hours following 0.2 Gm. of NU-903 and seven hours following 0.4 Gm., with those patients being taken into consideration who reported excellent or satisfactory results.

One subject receiving 0.2 Gm. and one receiving 0.4 Gm. complained of drowsiness upon awakening. Otherwise, there was a complete lack of untoward subjective reactions. Similarly, neither allergic phenomena nor other signs of idiosyncrasies were observed. This relative freedom from undesirable side effects offers a distinct advantage over the barbiturates, as evidenced by the fact that among the ninety-six patients treated for insomnia with NU-903 there were six persons who had experienced untoward reactions to barbiturates, such as excitability, excessive drowsiness, or skin reactions.

In the second group receiving NU-903 for daytime sedation, there were eighty-seven patients. About 60 per cent of these took amphetamine sulfate (30 mg. a day) for the purpose of weight reduction, and in these the experimental drug was given to overcome the nervous excitation induced by this stimulant.

Thirty-five patients received one-half tablet of NU-903 three times daily (total dose 0.3 Gm.), and fifty-two were given one tablet three times daily (total dose 0.6 Gm.). At the lower dosage level the average number of treatment days was fifteen, and at the higher dosage level it was twenty-one. However, eighteen patients received 0.2 Gm. three times daily for thirty days, and three for as long as ninety days.

The effects of this treatment are shown in Table IV. The degree of favorable responses was more difficult to ascertain than in the group receiving the drug as a soporific, and the therapeutic effects were therefore listed in a broader manner, by classifying them as satisfactory, fair, or none.

TABLE IV. TREATMENT OF NERVOUS TENSION WITH NU-903

DOSAGE	NUMBER OF PATIENTS	TOTAL NUMBER OF TREATMENT DAYS	RESULTS
0.1 Gm. t.i.d.	35	525	22 Satisfactory
			10 Fair
			3 None
0.2 Gm. t.i.d.	52	1,092	36 Satisfactory
			10 Fair
			6 None

As can be seen from Table IV, beneficial results were obtained in the majority of patients taking either 0.1 Gm. or 0.2 Gm. three times daily. The incidence of ineffectiveness of the drug as a sedative was about 10 per cent. It is not

easy to compare the responses to NU-903 with those to other sedatives because of the lack of objective criteria for such a comparison. Nevertheless, in eighteen patients who had received 0.2 Gm. of NU-903 three times daily, 30 mg. of phenobarbital, also given three times daily, were substituted for the experimental preparation. Six of these subjects claimed that they felt a greater degree of relaxation of nervous tension when they received NU-903. These observations give the tentative impression that the sedative effect of 200 mg. of NU-903 is somewhat superior to that of 30 mg. of phenobarbital. It may be inferred that on a weight basis, about four to five times as much of NU-903 as of phenobarbital has to be given in order to obtain the same degree of sedation. Untoward subjective reactions were conspicuous by their absence in all eighty-seven patients of this group. Likewise, there were no signs of idiosyncrasy. In this connection it is noteworthy that five of these eighty-seven subjects had previously reacted with a pruritic rash to barbiturate medication.

For ten of the patients receiving 0.1 Gm. of NU-903 three times daily for two weeks (included in Table IV), pre- and postmedication blood counts were done, including red, white, and differential counts, as well as hemoglobin determinations. There was no significant change in the blood picture of any of the subjects. In addition, a collateral study of a similar nature was carried out in nine persons not requiring sedative medication and, therefore, not included in the series that served for clinical evaluation of the experimental preparation. Each of these subjects received 0.1 Gm. of NU-903 three times daily for periods ranging from twenty-two to sixty-one days. The average number of treatment days was 38.2, and the total doses taken by the individual persons during the period of observation were as follows: 18.3, 12.6, 9.9, 12.9, 9.3, 6.6, 12.6, 13.8, and 7.2 grams. Hemograms, including differential counts and hemoglobin determinations, done at initiation and termination of medication revealed that there were no significant changes in the quality of the blood in any of the nine subjects.

SUMMARY AND CONCLUSIONS

A new sedative-hypnotic drug, 3,3-diethyl-2,4-dioxotetrahydropyridine, tentatively designated NU-903, was evaluated clinically in 183 patients. There were two groups of subjects: to one group, consisting of ninety-six patients, close to 1,000 doses of the drug were given to induce hypnosis, and to the other, consisting of eighty-seven patients, the preparation was administered as a daytime sedative for a total of over 1,600 treatment days. The results were as follows:

Four-tenths of a gram produced excellent or satisfactory sleep in thirty-two of forty-two patients. A dose of 0.2 Gm. proved less gratifying as a somnifacient, judged by results recorded for sixty-six patients. Of these, only thirty-two responded with excellent to satisfactory sleep, and the rest had poor or no results. However, in twelve in whom the lower dosage failed to produce gratifying results, satisfactory sleep was induced by 0.4 grams. In all subjects medication was given for at least seven consecutive nights.

For treatment of nervous tension, 0.1 Gm. of NU-903 three times daily was prescribed to thirty-five patients (average number of treatment days, fifteen).

and 0.2 Gm. three times daily to fifty-two individuals (average number of treatment days, twenty-one). Adequate sedation was obtained at both dosage levels in the majority of patients; there was no sedative effect in 10 per cent of the cases.

One subject receiving 0.2 Gm. and one receiving 0.4 Gm. as a somnifacient complained of drowsiness upon awakening. Otherwise, that is, in 181 patients, there was complete absence of untoward subjective reactions. No allergic phenomena were observed in any of the 183 cases treated. In contrast, eleven of these subjects experienced undesired aftereffects following barbiturate medication.

Blood studies carried out in nineteen subjects receiving 0.1 Gm. of NU-903 three times daily over prolonged periods of time did not reveal any untoward effects of the drug on the quality of the blood.

It can be concluded that NU-903 is an effective hypnotic and sedative which is distinguished by excellent tolerability.

LABORATORY METHODS

THE ASSAY OF HEPARIN

C. N. MANGIERI, B.S.

NUTLEY, N. J.

NUMEROUS methods for the standardization of heparin using citrated or oxalated whole blood or plasma have been described in the literature. Because of peculiarities in the development of clots *in vitro*, and the difficulty in distinguishing one from another, several means of determining an end point have been suggested. In Foster's¹ modification of the Reinert and Winterstein method, as many as eleven evaluations for various clot formations, ranging from a full clot to no clot, have been proposed. The assigned values are plotted logarithmically to determine the theoretic one-half clot. The method of Howell, as modified by Charles and Scott,² calls for the use of cat blood. Clot formations occurring in the standard heparin tube series are matched against those seen in the unknown series. Large differences in the clotting nature of cat blood renders difficulty in duplicating results. The method of Jacques and Charles³ utilizes oxalated beef blood with the addition of thrombin. Impurities in heparin samples interfere with the clotting mechanism and usually have a tendency to exaggerate their anticoagulant activity. The Fischer and Schmitz⁴ procedure using chicken blood does not permit the repetition of the assay under identical conditions. Knizenga, Nelson, and Cartland⁵ report that recalcified sheep plasma requires a smaller increment in heparin for a transition from coagulation to fluidity than either recalcified beef or horse plasma. They report that 2 μg (0.2 Toronto unit) of standard heparin containing 100 Toronto units per milligram are necessary for this complete change. In the method herein described, only 1 μg of such standard heparin is required to effect this change for recalcified beef or sheep plasma.

The evaluation of clots according to opacity, granulation, density, adherence to the walls of test tubes, traces, etc., is difficult. Values so assigned are subject to personal error of judgment and can lead to an erroneously plotted or matched end point. Experience has shown that two persons seldom evaluate or match clots identically. Also, slight modifications in the amounts of calcium, plasma or whole blood, saline, temperature, or time affect the development of clots to a noticeable degree. My experience is that a difference of as little as 0.05 mg. of calcium or 0.1 μg of heparin between two tubes containing 1.0 ml. of diluted citrated plasma or whole blood can cause an appreciable difference in clot formation. Such slight errors can easily be made in an assay, and their combined effects may be additive in determining the development of a clot.

From the Pharmacological Laboratories, Hoffmann-LaRoche, Inc., Nutley, N. J.
Received for publication, April 4, 1947.

My several years' experience with Foster's method, while working with him, has indicated possibilities for a simplified and improved heparin assay which are incorporated in the method herein described. The increment of heparin in each tube in a series is very small and constant, since only 1.0 μg . of the standard heparin is necessary to pass from clot to fluidity. The time which elapses between the addition of the calcium to the plasma is reduced to a minimum so that all tubes are treated identically. The end point is the least amount of heparin necessary to prevent any clot formation; it is definite and reproducible. Fresh or frozen⁶ citrated plasma can be used with equal accuracy.

PROCEDURE

Plasma.—Fresh beef blood is obtained in any desired quantity at the slaughterhouse. Flasks for holding the blood are prepared in the laboratory by placing therein 100 ml. of an 8 per cent sodium citrate solution and marking them at a 2-liter level. The blood is collected from the animals in paraffin-coated pitchers and immediately poured into the flasks to the 2-liter mark. The flasks are then stoppered and agitated gently. Upon reaching the laboratory, the blood is centrifuged at 2,000 r.p.m. for thirty minutes and the supernatant plasma is siphoned off and pooled. Each heparin sample to be assayed requires 12 ml. of plasma. Therefore, quantities slightly in excess of the amount required for an assay consisting of the standard heparin and any desired number of heparin samples are filled into Florence flasks. The flasks should be filled to approximately two-fifths of their capacity. They are then corked, frozen rapidly by rotation in a tilted position in an acetone dry ice bath, and stored in a refrigerator at -20°C .

Calcium Chloride Determination for Clotting.—The optimum calcium chloride level for recalcifying the plasma in this procedure must be determined for each new lot of fresh or frozen citrated plasma. This level is the amount of calcium chloride necessary to permit the end-point tube (the tube in which any clot formation has just been prevented by the heparin) in the standard heparin series to be located near the middle of the series. This quantity of CaCl_2 must be contained in a 0.2 ml. volume of physiologic saline which is used for each tube throughout the assay. The standard heparin should contain at least 100 Toronto units or 500 anticoagulant units⁷ per milligram.

When blood is citrated as previously described, usually 0.95 mg. of calcium chloride is necessary for the recalcification. However, the amount may vary slightly and can be determined in the following manner: To six tubes containing 0.35 ml. of a 10 μg per milliliter standard heparin solution is added, from the first to the last, 0.16, 0.18, 0.19, 0.20, 0.21, and 0.22 ml., respectively, of a 5 mg. per milliliter calcium chloride solution. Saline is added to bring the volume to 1.0 milliliter. Add 1.0 ml. of plasma and stopper with corks which have only the inserted face coated with paraffin (this prevents the corks from slipping out), invert two or three times, and place in a water bath at 37°C . for three hours. Then examine the tubes and select the one with the

most amount of calcium chloride having no clot formation. The amount of calcium chloride added to that tube is to be contained in the 0.2 ml. volume of physiologic saline mentioned. The concentration so determined can be used for all subsequent assays, using portions of the same plasma.

Assay.—The standard heparin powder and unknown finished powders are made up in concentrations of 10 μg per milliliter. Impure heparin powders, generally low in potency, are made up in concentrations of 20 or 40 μg per milliliter, depending upon their activities. One or two assays may be necessary to determine the concentration to use. Heparin vial solutions are diluted to a concentration of 1.0 Toronto unit per milliliter. Physiologic saline is used for all solutions. Acid-cleaned glassware is a prerequisite for an accurate assay. A series of twelve tubes (10 by 100 mm.) is used for the standard heparin and for each sample to be assayed. Microburettes are used for measuring the plasma and all solutions. To the first tube of the standard heparin series is added 0.23 ml. of the standard heparin solution; in each subsequent tube the amount of heparin solution added is increased by 0.02 ml. over the preceding tube so that the twelfth tube will contain 0.45 milliliter. Each unknown heparin solution is likewise measured into a series of twelve tubes. Saline is then added to all tubes to bring the volumes to 0.8 milliliter. A constant sequence is kept in adding the plasma and calcium chloride solution. To the first tube of each series add 1.0 ml. of plasma and 0.2 ml. of the calcium chloride solution; stopper with paraffin-coated corks, invert two or three times, and place in a water bath at 37° C. for three hours. Repeat this procedure for the second tube of each series and each subsequent tube until all the tubes have been so treated. By doing this, the influence of plasma changes is minimized. After three hours, the tubes are observed. That tube in each series in which any clot formation has just been prevented is the end-point tube for that series. The use of fluorescent light has been found most desirable for the detection of small clot formations. Very often a thin film of clot formation adheres to the rounded bottom of the tube; this is detected by inverting and uprighting the tubes rapidly once or twice in front of the lamp. The amount of heparin in the end-point tubes is used to calculate the potency of the unknown heparin represented by that series, in terms of the standard heparin.

Example.—The standard heparin potency is 110 Toronto units per milligram. To prevent clot formation, 3.1 μg of the unknown heparin powder and 2.7 μg of the standard heparin are required: the strength of the unknown heparin is 95.8 Toronto units per milligram.

$$\frac{110 \times 2.7}{3.1} = 95.8 \text{ Toronto units per milligram.}$$

If in this example, the unknown represented a heparin vial (10 mg. per cubic centimeter), diluted 1,000 times, the potency of 1.0 ml. of the original vial solution would be

$$\frac{110 \times 2.7}{3.1} \times 10 = 958 \text{ Toronto units per milliliter.}$$

DISCUSSION

The small increment of heparin permits an end point to be approached with a greater degree of accuracy than has heretofore been possible in other heparin assays. The increment makes it possible to detect with ease slight errors in titration in following the procedure because the diminution of the clot to fluidity is remarkably uniform in the series. This transition range, under the specific conditions of the assay procedure presented in this paper, requires only 0.1 Toronto unit of activity (1 μ g of standard heparin). Fresh and frozen citrated beef and sheep plasma have been used with the same degree of accuracy, and the transition from clot to fluidity requires approximately the same heparin activity. It is, however, easier to determine traces of clot formation in beef plasma than in sheep plasma. Also, it is easier to obtain beef plasma, in large quantities, than sheep plasma, and the results obtained are more uniformly duplicated. Repeated tests on various concentrations of the standard heparin used in this laboratory yielded results within ± 10 per cent of the theoretic potencies.

SUMMARY

1. A method for the assay of the anticoagulant activity of heparin using recalcified fresh or frozen beef or sheep plasma has been presented.
2. The end point is definite.
3. The method is rapid, simple to execute, reproducible within less than 10 per cent error, employs simple calculation for potency determination, and enables the repetition of the assay using the same material under similar conditions of assay.

PERMANENT METACHROMATIC STAINING OF MUCUS IN TISSUE SECTIONS AND SMEARS

MANFRED HESS, M.D., AND FRANKLIN HOLLANDER, PH.D.
NEW YORK, N. Y.

THE cytology of mucous secretion in the digestive tract has been neglected as a field of investigation in gastroenterology, in part because of the lack of a satisfactory staining method for the mucins. The only stain for this purpose which has withstood the test of time is mucicarmine, and this has been reliable only for mucus in typical goblet cells. In the stomach, where the mucins normally occurs in the columnar surface epithelium and the neck chief cells, its reliability is notably poor. Thionine and toluidine blue are examples of another type of mucin stain. These dyes differentiate sulfuric acid esters of high molecular weight (for example, the mucins) from other tissue components by a characteristic bichromatic effect called metachromasia, and thereby obviate the need for counterstaining for this purpose. In the case of toluidine blue the mucins are stained some shade of red or purple, whereas other cellular components are stained blue. In addition to this advantage, the metachromatic stains are superior to mucicarmine in respect to their sensitivity and specificity. For these reasons, toluidine blue or thionine would long ago have become the preferred mucin stain were it not for the fact that their characteristic bichromatic effect is lost as soon as the stained tissue is subjected to any dehydrating procedure.

Some time ago we³ reported a technique for permanent metachromatic staining which was suitable for smears of viscous gastric mucus but not for tissue sections. When this method was applied to smears of secretion from gastric pouches stimulated with mustard oil, or to smears of human gastric juice, it often resulted in the loss of most of the material during the staining process. Although tissue sections were stained effectively, the metachromatic effect was transient. Furthermore, smears treated in this way frequently showed disintegration of the cytoplasmic portion of the cells, but the nuclei were well preserved.

The present investigation was undertaken in an effort to overcome these major deficiencies. To this end, it was necessary to reconsider every step in the procedure and to test it repeatedly on a variety of tissues from animals of different species, as well as on mucus from dog and man.

Fixation.—Smears of mucous material gave excellent results after simple air drying, without chemical fixation. For tissues, a number of fixatives were tried without success. Ten per cent formalin failed to preserve the mucus effectively and stained connective tissue red as well. After fixing with Helly's

From the Gastroenterology Research Laboratory, The Mount Sinai Hospital.

Received for publication, April 18, 1947.

fluid the tissue took the dye, but poorly. A saturated solution of mercuric chloride led to considerable shrinkage and caused precipitation of the dye. A saturated solution of mercuric chloride containing 5 per cent acetic acid gave irregular, granular staining. Alcohol-formol or 70 per cent alcohol alone prevented staining of mucinous substances altogether. The one fixative which gave truly satisfactory results was Zenker's solution with acetic acid, prepared without the addition of sodium sulfate. Neither potassium bichromate nor mercuric chloride alone yielded the same degree of color intensity and brilliance as a mixture of the two. This fixative preserved both intra- and extracellular mucus and augmented the contrast between the metachromatic and normochromatic structures without inducing a diffuse metachromatic staining of the connective tissue. Another advantage was preservation of cytologic detail. Toluidine blue is in general an excellent nuclear stain, but its efficiency in this regard is markedly increased by Zenker's fixation.

Staining.—After repeated trials under a variety of conditions, the staining solution finally adopted contained 0.25 Gm. of toluidine blue per 100 ml. of 0.25 per cent borax solution. When the dye was more dilute than this, it did not stain deeply enough, whereas more concentrated solutions led to a diffuse purple staining of all structures with practically no bichromatic differentiation. The pH of the staining solution is fixed about 9.0 by the borax. It was found that most of the tissues could be stained well also with a simple aqueous solution of the dye (pH 5.5), except for the surface epithelium of feline and human stomachs. In these two instances, the intracellular mucus failed to take the dye unless the pH of the staining solution was adjusted to 9.0, a value which was found to be adequate for all the other tissues and all the smears. After the usual processing of the paraffin sections from xylol to water, it was found desirable to rinse the slides in a fluid of about the same pH (for example, 0.25 per cent borax) both before and after staining. Smears are rinsed only after being stained. The optimal staining time was thirty seconds for all materials examined. Any prolongation beyond this limit leads to overstaining and a nonspecific purple coloration. There is a tendency for the connective tissue to be stained metachromatically at this stage, but this usually disappears during subsequent treatment.

Preservation of Metachromasia.—Ever since the investigations of Hoyer⁵ it has been known that the metachromatic effect disappears as soon as the stained sections are treated with alcohol. Attempts have been made to overcome this difficulty by mounting the water-wet preparation directly in a glycerine-containing medium or in a levulose syrup⁹; also, by dehydrating with acetone instead of alcohol⁷ before treatment with xylol for mounting in balsam. All of these techniques failed to give us the desired permanence, as did a multitude of other empiric procedures. It was finally found that metachromasia can be preserved if the stained and washed section is treated with an aqueous solution of 0.5 per cent potassium bichromate, saturated at room temperature with mercuric chloride.

Dehydration and Mounting.—Following this treatment with bichromate-sublimate solution, the slide is washed with absolute alcohol. If other than

anhydrous alcohol is used, connective tissue, smooth muscle fibers, and even some nuclei acquire a red coloration. It also happens that an occasional finished preparation shows streaks of blue dye. Both of these irregularities can be prevented if each slide is rinsed thoroughly with a stream of fresh absolute alcohol from a siphon bottle, instead of being immersed in a staining dish containing alcohol which has become diluted from repeated use. Omission of the usual treatment with graded concentrations of alcohol does not lead to any considerable shrinkage. At this stage of the procedure the section shows excellent metachromasia, but when it is brought into xylol all its elements acquire a bluish coloration. With this reduction in reddish tones the normochromatic elements become a purer blue, but there is a loss in sharpness of the metachromatic differentiation. Such purification of color tone in the normochromatic elements is distinctly advantageous, and it can be retained even when the metachromasia is reintensified by the next step; that is, retreatment with absolute alcohol followed by the bichromate-sublimate mixture. The section is then washed with absolute alcohol containing 1 per cent of rosin, which intensifies the red shades with toluidine blue as it has been shown to do with Giemsa stain. The slide is then carried through two changes of benzol and mounted in Canada balsam dissolved in benzol. The use of xylol, toluol, or acetone for clearing or as solvent for the balsam must be avoided because they destroy the metachromasia. Clarite may be substituted for benzol-balsam, but the results are less satisfactory.

OUTLINE OF THE STAINING TECHNIQUE

Tissues are fixed in Zenker's solution containing 5 per cent acetic acid, and the paraffin sections are carried through to water in the usual way. They are then rinsed in 0.25 per cent aqueous borax solution and drained free of surplus fluid. Smears are prepared from mucus specimens immediately after collection and are left to dry at room temperature for the *minimum* time required. This is usually two to four hours. Mucous smears are not given the preliminary rinsing in borax solution. Slides of both smears and tissue sections are then treated as follows:

1. Cover for thirty seconds with ample staining solution (0.25 Gm. toluidine blue 0* dissolved in 100 ml. of 0.25 per cent borax solution).
2. Rinse with 0.25 per cent borax solution.
3. Cover for fifteen seconds with a 0.5 per cent solution of potassium bichromate, which has been saturated with mercuric chloride at room temperature and filtered, and drain.
4. Cover the slide for two minutes with a fresh portion of the bichromate-sublimate solution and drain.
5. Wash thoroughly for about ten seconds with a stream of fresh absolute alcohol from a siphon bottle.
6. Immerse in xylol for thirty seconds.
7. Rinse again with absolute alcohol and drain completely.

*National Aniline, Certified.

8. Cover again with the bichromate-sublimate solution for thirty seconds.
9. Rinse thoroughly with rosin alcohol (1 Gm. rosin, U. S. P., dissolved in 100 ml. absolute alcohol) and drain.
10. Carry through two changes of pure benzol (one minute each).
11. Mount in Canada balsam dissolved in benzol.

DISCUSSION

In order to assure ourselves of the permanence of the metachromatic differentiation obtained by means of the foregoing procedure, it was applied to a variety of tissues in May, 1945. For this purpose specimens from stomach, jejunum, colon, salivary glands, and bronchi were obtained from the dog, cat, rat, guinea pig, and rabbit. Specimens of resected human stomachs, taken at operation, and guinea pig cervix were also included, as were smears of mucus collected from Heidenhain pouch dogs and human stomachs under engorgement stimulation.⁴ At the time of this report, two years after preparation, these slides continue to show excellent preservation of metachromatic as well as normochromatic colors. Only in the goblet cells of rat jejunum is there any evidence of a loss of metachromasia, but even in this instance some areas of the section still contain purple-stained material.

Various theories have been advanced to account for the metachromatic properties of certain dyes like toluidine blue.^{1-3, 12, 6, 8} Recently, Michaelis and Granick⁹ added quantitative spectrophotometric evidence to support the view that the shift from blue to purple is due to polymerization of the dye molecules. The simple monomeric form possesses the normal color (pure blue), whereas the polymers are purple to pink, depending on the degree of polymerization. Increasing the concentration of dye induces a shift in color toward the purple, even in the absence of a metachromatically staining substance,¹⁰ and this change is completely reversible on subsequent dilution. This effect is readily explained by the polymerization theory. Alcoholic solutions of the dye show only the blue coloration, and treatment of metachromatically stained substances with alcohol invariably leads to a disappearance of metachromasia. This reversal can be prevented by the action of a mixture of potassium bichromate and mercuric chloride on the metachromatic complex of dye and substrate. As yet, no explanation has been offered for either the deleterious effect of alcohol on metachromasia or the stabilizing effect of the bichromate-sublimate mixture. It is interesting, however, that treatment with the latter does not induce metachromatic staining of previously normochromatic structures; it merely preserves and improves the effects which are already existent.

The superiority of the present technique over that previously reported by us may be ascribed to the change in pH of the staining and washing fluids from an acid value (circa 3) to an alkaline one (circa 9). As a result, cytoplasmic destruction in smears is eliminated and loss of material from the slide is prevented. Although the success of this method in tissue sections depends largely upon this different pH, it is the use of the bichromate-sublimate mixture which effects the permanence of the metachromasia. On the other hand, the present

procedure possesses certain obvious disadvantages. Occasionally the finished preparations of smears, but not of paraffin sections, contain residues of bichromate which give a disturbing yellow-green coloration in some areas, and as yet we have not been able to eliminate this. Also, the method is applicable only to tissues which have been fixed in Zenker's solution; if it could be used after formalin and Bouin's fluid, this would be a decided advantage for the purposes of the routine pathology laboratory. We hope that these difficulties may also be overcome in time and that the entire procedure may be simplified.

We wish to express our thanks to Dr. B. P. Sonnenblick, who stained a great variety of tissue sections and smears by this method in order to confirm our experience with it.

RETICULUM STAINING WITH SCHIFF REAGENT AFTER OXIDATION BY ACIDIFIED SODIUM PERIODATE

R. D. LILLIE,² BETHESDA, MD.

WITH THE ASSISTANCE OF A. LASKEY, J. GRECO, AND H. JACQUIER

THE method to be reported herein was evolved from studies on the relation of the Baner¹ glycogen method to the Jackson-Hudson² periodate oxidation of polysaccharides. These studies are being published elsewhere in extenso.

Glycogen, epithelial mucin, cellulose, starch, yeast, and mold chitin and cartilage matrix are stained purplish-red by the Baner technique.³ When an acid sodium periodate solution is substituted for the chromic acid of the Bauer method, reticulum of certain parenchymatous organs, notably lung, kidney, thyroid, and cerebral capillaries, is stained a brilliant purplish-red; collagen and fibrin, pink. Capsular substance of certain bacteria and certain elements in Actinomyces granules also stains pink, but further detailed studies are necessary on this.

The technique employed is as follows:

1. Thin (5 μ or less) paraffin sections of routine material fixed in formalin, Orth's fluid, or other fixatives are deparaffinized and brought to 100 per cent alcohol as usual.
2. Soak five minutes in 1 per cent collodion in 50:50 ether and 100 per cent alcohol mixture. Drain one minute with slides held vertically, and harden five minutes, or as much longer as convenient, in 80 per cent alcohol.
3. Wash in water and immerse for ten minutes in sodium periodate (Na_2IO_5), 1 Gm.; 70 per cent nitric acid (specific gravity, 1.42), 0.5 c.c.; distilled water, 100 cubic centimeters.
4. Wash five minutes in running water.
5. Immerse for fifteen minutes in Schiff reagent,[†] agitating at three- to five-minute intervals, preferably by pouring the fluid out and back.
6. Transfer directly to three successive baths of one and one-half minutes each in 0.5 per cent sodium bisulfite (NaHSO_3). (This is slightly weaker than Bensley's⁴ M/20.)

From the Pathology Laboratory, National Institute of Health, U. S. Public Health Service.

Received for publication, May 5, 1947.

*Medical Director, U. S. Public Health Service.

†The Schiff reagent is made as follows: Dissolve 1 Gm. basic fuchsin in 100 c.c. distilled water at 90 to 95° C.; filter while cooling at about 60 to 70° C. When cool, add 2 Gm. sodium bisulfite (NaHSO_3) and 20 c.c. normal hydrochloric acid; stopper tightly; put away in cool, dark place overnight. In the morning the solution should be somewhat brownish-yellow in color. Add 300 mg. of finely ground charcoal, shake for one minute, and filter. The solution should become pale yellow. Store in refrigerator at 0 to 5° C. The solution may be used for several weeks, at least if kept cold. Discard if a pink color appears.

7. Wash ten minutes in running water.
8. Stain five to six minutes in Weigert's¹ acid iron chloride hematoxylin. Wash in water.
9. Counterstain one minute in saturated aqueous picric acid solution or in 1 per cent orange G.
10. Dehydrate with alcohols and clear in one change of xylene and 100 per cent alcohol mixture (50:50) and two changes of xylene; mount in clarite.

The Weigert fibrin routine may be introduced in place of steps 9 and 10.

- a. Stain in Conn's² ammonium oxalate crystal violet (or any other aqueous or hydroalcoholic crystal violet) for two or more minutes.
- b. Wash off quickly with 0.9 per cent sodium chloride solution.
- c. Treat with the Weigert-Lugol³ iodine solution (1 Gm. iodine, 2 Gm. potassium iodide, 100 ml. distilled water) for thirty seconds.
- d. Blot dry with hard filter paper and decolorize with several successive changes of a few drops each of aniline and xylene (50:50) mixture until violet color ceases to come out.
- e. Wash in two or more changes in xylene; mount in clarite.

RESULTS

By all three variants discussed, pulmonary reticulum, renal reticulum, and glomerular stroma, the reticulum of intestinal smooth muscle, the subepithelial basement membrane, the supporting stroma of the cerebral capillaries, and the reticulum of the gastric mucosa were stained a bright purplish-red. Collagen stains pink. Fibrin, hyaline droplets in renal epithelium, hyaline casts, and serous coagula in pulmonary alveoli also stain dull pink of a variable intensity when no plasma stain or the picric acid or orange G variants are used. With the Weigert fibrin variant, fibrin, hyaline droplets, and serous coagula vary from pink to violet, and red corpuscles stain gray to blue-violet. Orange G tinges the erythrocytes orange-yellow but has little other evident effect. Picric acid gives bright yellow erythrocytes and yellow to brown cytoplasm, and gives a yellow overcast to the pink of fibrin, serum, and the like.

With all variants, cartilage matrix is stained red-purple; epithelial mucin, reddish-purple to almost violet; glycogen, dark red-purple to almost black. If confusing, the glycogen may be removed by interposing the Lillie-Greco⁴ diastase digestion technique between Steps 1 and 2.

McManus⁵ reported the use of a periodic acid Schiff technique for the demonstration of mucin, and recently presented the extension of this technique to the demonstration of renal capillary stroma.*

THE QUANTITATIVE DETERMINATION OF AMPHETAMINE

WILLIAM D. McNALLY, A.B., M.D., W. L. BERGMAN, Ph.C., J. F. POLLI, B.S.
CHICAGO, ILL.

A SATISFACTORY and shortened method for the quantitative recovery of amphetamine from human organs was evolved following repeated experiments *in vitro*.

Because of the ever-widening use of beta-phenylisopropylamine, variously sold under the name of Amphetamine, Benzedrine, Elastonon, Isoamin, Necedrin, and Orledrin, a study was undertaken to obtain an efficient method of quantitative determination of amphetamine. A technique of extraction is described, using a sulfuric-tungstic acid filtrate, as well as a method of quantitative determination; these greatly reduce the time element in the separation of amphetamine from human organs.

We have used a new technique of approach, employing a combined method of purification, distillation, and diazotization, which is presented in detail.

METHOD

To 25 Gm. of blood, urine, or finely minced organs in a 1 liter flask, add 150 ml. of distilled water. Shake well for five minutes and allow to stand for ten minutes longer. Add 10 ml. of 10 per cent NaOH and shake well for five minutes; then add 30 ml. of 10 per cent sodium tungstate and shake well. Next add slowly 30 ml. of 1 N-H₂SO₄ with continuous shaking, and finally acidify with 18 N H₂SO₄ and add 5 ml. in excess. Allow to stand for fifteen minutes and filter through a No. 12 Whatman folded filter paper. Transfer the filtrate to a 1 liter round bottomed flask and make neutral with 10 per cent NaOH; then add 1 ml. in excess. Steam distill through a short neck flask connected to a Liebig condenser and collect 200 ml. of distillate in a flask containing 10 ml. of 4 NH₂SO₄. Transfer the distillate to a 500 ml. extraction flask, add 20 ml. of ether and make alkaline with 10 per cent NaOH and add 1 ml. in excess. Shake the flask for one minute and extract with three more portions of ether. Combine the ether extracts, wash with water, and discard the water. Extract the ether layer with three 10 ml. portions of 0.5 per cent HCl. Evaporate the HCl extract to dryness over steam bath and diazotize as follows:

Take up residue with 1 ml. of water and add 5 ml. of cold diazotizing reagent (keep volume below 2 ml. for a larger volume of water causes a reduction of color due to failure of complete reaction with diazotizing reagents). Then add 5 ml. of 1.1 per cent sodium carbonate drop by drop with continuous mixing and allow to stand for fifteen minutes. Next add 1 ml. of 10 per cent NaOH drop by drop with continuous mixing and allow to stand for ten minutes. Dilute with water to 40 ml. and mix. Add 10 ml. of n butanol and mix by inverting. After colored layer has cleared, read transmission in spectrophotometer at 530 mμ and calculate the amount of amphetamine present from a standard curve.

Nicotine and pyridine do not interfere with the above separation. The amphetamine is identified in an aliquot part of the distillate by obtaining the melting point of the picrate (142° to 143° C.) and the picrolonate (195° to 196° C.)

REAGENTS¹

1. p-Nitroaniline Hydrochloride

To 0.69 Gm. p-nitroaniline in a 125 ml. glass-stoppered Erlenmeyer flask, add 3 ml. of concentrated HCl. Mix by twirling and break larger lumps with a glass rod. Let stand for ten minutes from the time of addition of the acid. Add 97 ml. of distilled water, a little at a time, with continuous mixing. Stopper the flask and shake vigorously. Filter on a 9 cm. Whatman No. 4 paper, collecting filtrate in a 125 ml. glass-stoppered Pyrex bottle. This solution should be stable at room temperature for at least a year.

2. 0.7 Per Cent Sodium Nitrite (NaNO_2)

Dissolve 0.7 Gm. reagent grade NaNO_2 in distilled water and dilute to 100 milliliters. This solution should be refrigerated at all times and should not be used after it is more than one week old.

3. Diazo Reagent (p-Nitrobenzenediazonium Chloride Solution)

To 5 ml. p-nitroaniline hydrochloride in a 100 ml. glass-stoppered volumetric flask, add 1 ml. of concentrated HCl. Place the flask in an ice-salt bath for ten minutes and then add 3 ml. of 0.7 per cent solution of sodium nitrite. Let stand in ice-salt bath for six minutes, dilute to volume with distilled water (room temperature), mix, and return to ice salt bath for ten minutes. The reagent is now ready for use and will keep at 0 to 1° C. for at least two weeks under these conditions. It should be tested with amphetamine sulfate standard before using it with unknowns.

4. 1.1 Per Cent Sodium Carbonate (Na_2CO_3) Anhydrous

Dissolve 2.75 Gm. Na_2CO_3 (reagent grade) in distilled water and dilute to 250 ml. in a Pyrex bottle.

5. 10 Per Cent Sodium Hydroxide

Made to contain 10 Gm. NaOH in 100 ml. solution; store in a rubber-stoppered 250 ml. Pyrex bottle.

6. n-Butanol

7. Standard Amphetamine Sulfate*

Made to contain 0.03 mg. amphetamine sulfate per cubic centimeter.

Beyer and Skinner¹ described a new method for amphetamine determination in urine. By diazotizing the extracted amphetamine with p-nitrobenzene, they obtained a red color which was intensified by shaking out with n-butanol.

Gad² described a distillation method for tissues. His distillate was collected in 25 ml. of 4 N H_2SO_4 . The distillate was made alkaline, then extracted with benzol, and the benzol portion then extracted with 0.02 N HCl. The unused portion of the acid was titrated with 0.02 N sodium hydroxide using methyl red as indicator. Gad also used the spectrophotometer in estimating the amount of amphetamine. The objection to his method was the length of time required and consequent tediousness, as a result of its troublesome foaming.

Using Gad's method, we found that post-mortem material, amphetamine-free, induced a color reaction when tested by the Beyer and Skinner method. We then subjected our distillate, using a sulfuric-tungstic acid filtrate, to the Beyer and Skinner method of estimation of amphetamine, and the result was a colorless blank. With known quantities, a well-defined color was obtained, which could be compared with suitable standards.

Table I is presented to demonstrate that amphetamine is quantitatively recoverable from the liver.

*Smith, Kline and French Laboratories.

TABLE I. RECOVERY OF ADDED AMPHETAMINE SULFATE FROM 25 GM. OF LIVER

EXP.	NaOH CONC.	MG. OF AMPHET- AMINE SULFATE ADDED	ML. DISTILLED	MG. RECOVERED	% RECOVERY
1	10%	1.0	250	0.20	20
2	5%	1.0	600	0.43	43
3	1 ml. of 10% NaOH in excess	1.0	100	0.98	98
4	1 ml. of 10% NaOH in excess	2.0	200	1.80	90
5	1 ml. of 10% NaOH in excess	1.0	200	0.95	95
6	1 ml. of 10% NaOH in excess	1.0	200	0.95	95

The precipitated protein residue was tested for the presence of amphetamine with negative results. The distillation was conducted at a pH of 8.

Fig. 1.

Many other investigators have advanced methods of amphetamine distillation. Among them was Schoen,⁴ who distilled a tablet into standard sulfuric acid and titrated the unused acid. Keenan¹ described a gold chloride micro-precipitation method. Reznek⁵ extracted solutions of amphetamine from alkaline solutions with chloroform. The chloroform was extracted with 0.1 N H₂SO₄, and the unused acid was titrated with 0.1 N alkali (1 ml. of 0.1 N acid was equal to 0.0135 Gm. of amphetamine). Dultz⁶ used a method for detecting beta-phenylisopropylamine, and beta-phenylisopropylmethylamine based on the determination of the melting points of the picrolonates. Cannon⁷ described a microchemical test with platinum chloride, a second method using a benzol derivative with a melting point of 134° to 135° C., and a third method based on coupling with p-nitrobenzene diazonium chloride. This same author⁸ later described a modified technique for amphetamine determination and reported a collaborative study of previously described methods. Illing⁹ reported that the distillation of alkaline mixtures of viscera was practically impossible and that when acidified with acetic acid the distillate gave negative results for amphetamine.

These methods for the most part were found wanting, for our observations, from repeated experiments, indicated that the distillation method alone or the tungstate precipitation without distillation gave interfering color.

Our application of distillation and extraction procedures to aqueous solutions of amphetamine sulfate gave quantitative recoveries. This combined method of purification of organs by precipitation with sulfuric and tungstic acid gave clear solutions which filter rapidly. The method will detect and estimate as low an amount of amphetamine as 0.03 mg. in 25 Gm. of tissue. It can be applied to blood and urine as well as to tissues and does not require a blank to be subtracted.

We found the time for quantitative separation from tissues greatly reduced with this method and found it to be a much shorter procedure than the usual modified Stas-Otto method, used routinely in our laboratory.¹⁰ Another salient feature was the elimination of foaming which was encountered in the Gad distillation.

SUMMARY

A new quantitative method for the determination of amphetamine in organs, using sulfuric-tungstic acid filtrate, distilled, is described.

It is shown that quantitative recoveries were obtained from the application of distillation and extraction procedures to aqueous solutions of amphetamine.

This method is applicable to blood and urine as well as to tissues. It will estimate an amount of amphetamine as low as 0.03 mg. in 25 Gm. of tissue.

A MICROSCREW CLAMP FOR USE WITH MOHR TYPE OF MICROBURETTES

R. H. K. FOSTER, M.D., AND A. G. BROEKER
St. Louis, Mo.

THE Koch* microburette, in common use for many years, consists of a small capacity burette, 1 to 10 ml., graduated in 0.01 or 0.05 ml., and connected to a reservoir through a glass stopcock. A troublesome feature inherent with any apparatus having glass stopcocks is the gradual accumulation of particles of grease and a film of grease which prevents wetting of the wall of the graduated tube. This results from gradual loosening of the grease by repeated turning of the stopcock. No lubricant, including silicone, overcomes this difficulty. Frequent treatment with cleaning solution is necessary and involves a lot of time and labor. With heparin assays, acid cleaning after every assay is found necessary to give a good meniscus. Another disadvantage is that after several manipulations the accumulation of grease on the margin of the stopcock bore forms a sort of flap valve which makes accurate control impossible. Control of the flow also becomes difficult as the lubricant becomes thinned out and emulsified with consequent sticking.

To obviate these difficulties a microscrew clamp to use with rubber tubing has been designed. The first consideration was to provide a thumbscrew that would work easily yet without play. Second, a shut-off stop was needed to limit the compression of the rubber tubing just enough to stop the flow. Third, an opening stop seemed desirable to permit instant opening to a predetermined degree. This would regulate the maximum rate of outflow from the burette. The main features of the clamp will be described although Fig. 1 is self-explanatory. A photograph of the clamp is shown in Fig. 2.

The screw clamp shown is designed to take a $\frac{5}{16}$ inch outside diameter pure gum tube, but the clamp may be made for any size. The rubber tube is maintained in position by four pins. A U-shaped clamp, shown in the lower part of the front view and in section A-A, is fitted over the lower end of the rubber tube in which is inserted the glass delivery tip and holds the latter steady.

The clamp is held together by two threaded rods, an extension of one serving as the stop. The compression bar is slightly rounded on its contact surface. A strong bronze spring forces the compression bar assembly firmly against the lower end of the thumbscrew through a steel ball bearing. Play is thus eliminated and friction in the step bearing minimized. The thumbscrew turns in a threaded bronze bushing, and the large knurled knob provides for fine control

Received for publication, May 2, 1917.

From the Department of Pharmacology, St. Louis University School of Medicine.

The Project for which this microscrew clamp was developed was supported by a grant from the United States Public Health Service.

These microscrew clamps may be obtained from Earl L. Page, Nashville, Ind.

*Koch, F. C.: Two Convenient Forms of Apparatus for Microblood and Microurine Analysis, J. LAB. & CLIN. MED. 11: 774, 1926.

The two adjustable stop levers are threaded to fit the shaft of the thumb screw. Any degree of compression on closing is obtainable, and any degree of opening up, to a turn of about 330 degrees. Loosening both levers permits opening to the maximum distance as needed when inserting the rubber tube, or in draining and cleaning the burette. The entire assembly is supported by a $\frac{3}{8}$ inch rod clamped to a suitable support. Except for the steel ball bearing, all parts are of nonferrous metal.

The lower end of the microhurette has a side outlet for connecting to the reservoir. This outlet is placed 45 degrees to the rear on the right side so that both the microscrew clamp and another smaller screw clamp controlling the reservoir may be operated by the right hand.

Fig. 1.

The change in liquid level in the burette due to compression of the rubber tubing after closure is reduced to a small and constant value by setting the closing stop lever to a point where the flow is just stopped. The volume of the liquid displaced may be as little as 0.001 or 0.002 ml. and depends partly on the quality of the rubber tubing. Skill is quickly acquired in compensating for this when definite volumes are being dispensed. In titrations there is no concern for this since readings are made only after closure.

It has been found that this microscrew clamp offers an ease of manipulation quite outside the range provided by glass stopcocks. In heparin assays several hundred portions of solutions have been dispensed from a series of microburettes. One's fingers become tired in adjusting the glass stopcocks, even to the point of being unable to control accurately a stopcock still turning smoothly. This microscrew clamp virtually eliminated fatigue in the experiments run, and the speed of operation was increased. Volumes as small as 0.001 ml. may be dispensed if the burette bore is small enough. A microburette with this specially designed screw clamp should be useful not only in heparin assays, but also in many types of work where small volumes are to be dispensed, or for microtitrations.

Fig. 2.

SUMMARY

A microscrew clamp has been described for use with microburettes which offers the following advantages over glass stopcocks:

1. Minute control to 0.001 ml. is possible.
2. Faster operation is attained through the use of adjustable stops for the open and closed positions.
3. Faster operation is also attained by the greater ease of manipulation which also reduces fatigue.
4. The frequency of the troublesome acid cleaning is reduced by the elimination of the glass stopcock; and because there is no lubricant to collect on the glass walls, cleaning time itself is reduced.

AN INSTRUMENT FOR RECORDING MULTIPLE PRESSURES IN MAN

GEORGE S. EDWARDS, M.D.†

LOS ANGELES, CALIF.

Introduction.—The instrument to be described was developed in order to record multiple pressure changes used in study of the cardiovascular system. These are intra-arterial pressure, pneumatic cuff pulsations and pressure, finger plethysmograph, venous pressure, and respiration. This instrument does not represent an original development as to principle, but it is felt that the modifications and adaptations of previously published techniques have proved to be of sufficient practical value to be described. It was also felt that the method of optical recording with high frequency manometers described by Hamilton and co-workers,¹ and subsequently modified for special purposes by various authors (Green,² Gregg and associates,³ Kotte and associates,⁴ and Cahoon and co-workers,⁵ was the simplest and most accurate available. However, the relatively long optical levers proved to be too cumbersome for general clinical use in a hospital, where it was desirable to have an instrument that could be transported from one ward to another and used in well-lighted rooms. Portability coupled with the necessity for recording four to six pressures simultaneously required considerable modification of the usual optical manometers.

General Description (Fig. 1).—The present instrument consists of three separate units (Fig. 1). One (A, Fig. 1) houses the light source, transformer, manometers and holders, and timing device. It measures 81.28 cm. (32 inches) in length, 38.10 cm. (15 inches) in width, and 35.56 cm. (14 inches) in height. The second unit (B, Fig. 1) is the photokymograph or camera, the base of which is 21.59 cm. (8½ inches) square and the height, 30.48 cm. (12 inches). This construction enables the camera to be used for other purposes. The third unit (CPS, Fig. 1) contains a compressed air tank, pressure indicators, and control valves for inflation and deflation of a pneumatic cuff.

Optical System (Fig. 2).—The optical system employed resembles in principle those previously described in that it consists of a light source, the beam of which is reflected from a small mirror mounted on an elastic membrane to moving photographic film (Fig. 2). It is so arranged that the optical length from the mirror to the film is 80 centimeters. The light source consists of a battery of inverted "V" filament 6-volt bulbs arranged to give a vertical filament image. The lights are enclosed in a small plywood housing and require no special ventilation. A cylindric lens which corrects the image of the lamp filament in the vertical axis is placed in front of each manometer. Mounted in the camera is a cylindric lens which corrects the image of the lamp filament in a horizontal axis, thus producing a square or rectangular spot on the film.

From the Department of Physiology of the School of Medicine of the University of Southern California.

Received for publication, March 6, 1947.

†Dr. Edwards died on Jan. 6, 1947.

Timing Device.—The timing device, giving transverse lines at 0.10 second intervals, consists of a lamp with a rotating slotted disk between it and the camera. The disk is driven by a synchronous motor.

Fig. 1

Fig. 1.—General assembly. A, Housing for light source, transformer, manometers and holders, and timing device; B, camera; CPS, compressed air tank, pressure indicators, and control valves for inflation and deflation of cuff.

Fig. 2

Fig. 2.

Manometers.—The diameter and tension of the manometer membranes vary with the type of pressure to be recorded. Latex rubber is used. For the lowest pressure range (plethysmograph), a large slack manometer membrane (diameter, 2.5 cm.) is used. For intra-arterial pressure recordings, which are in the highest pressure range, tense membrane manometers of 0.5 to 1 cm. in diameter are used. Recently, beryllium copper has become available again and is replacing the latex membranes in higher pressure ranges.

Manometer Holders (Fig. 3).—Each manometer assembly is mounted on a small platform on which it can be rotated around a vertical axis so as to place

the reflected light beam at any position along the camera slot. This position is maintained by a single clamping screw. The block (A, Fig. 3, Part C) containing the manometer tube rotates on an axis parallel (around pin P, Fig. 3, Part C) to the camera slot and may be clamped in position by a single screw. This movement serves to elevate or depress the reflected light beam in relation to the camera slot. The manometer tube is inserted into a hole in this block so that it may be rotated 360 degrees around a horizontal axis perpendicular to the camera slot and may be clamped in any position by a single screw. This allows the axis of deflection of the light beam to be made parallel to the camera slot (horizontal). The assembled manometers are shown in Fig. 3, Part D.

Tubing.—The tubing used to connect the intravascular needles with the manometer should be relatively nonexpansible lest serious damping of the system occur. Polyethylene plastic tubing (I.D., ± 1 mm.; wall, ± 2 mm.) has been found to have several distinct advantages over lead, tin, or zinc tubing. It is chemically inert to the solutions that it contains and therefore forms no precipitate, and it is transparent so that air bubbles may be readily observed. Its flexibility makes it easy to handle.

With the advent of small diameter thin-walled polyvinyl tubing which may be passed through 17- or 15-gauge needles, the possibility of utilizing this material and discarding the rigid indwelling needles has been considered. A flexible tube which is relatively inelastic and has a large inside diameter as compared with the outside diameter has many theoretical advantages for intravascular studies. In addition the clotting time of blood in such a tube is greatly prolonged as compared with that in a steel needle tube. For veins, a 17-gauge needle is introduced into the vein and a length of polyvinyl tubing inserted through the needle within the vessel for several centimeters (or any desired length); the needle is then withdrawn, leaving the tubing within the vessel. It is then connected to a manometer by a suitable adapter and flexible tubing. Little bleeding takes place around the indwelling tube.

Finger Plethysmograph.—The usual water-filled glass tube plethysmograph has been replaced by an air-filled thin-walled aluminum tube 12 cm. (4.72 inches) in length and 3.5 cm. (1.38 inches) in diameter, which is equipped with a screw-on collar that allows cones with openings of various diameters to be fastened to the tube. The plethysmograph tube with cone in place is slipped over the finger and one of the quick-drying liquid plastics is applied. By this method only relative changes in volume which take place over short periods of time such as with acute venous occlusion (finger blood flow) may be measured.

Differential Chamber (Fig. 4).—To record the arterial pressure pulses transmitted through a pneumatic cuff, a manometer must be able to withstand cuff pressures up to 300 mm. Hg or more, yet be responsive to pressure changes of 1 to 5 mm. Hg. The differential capsule principle has been utilized and a small chamber which fits in the described manometer holders has been developed. The membrane holder is screwed into the manometer tube in the usual fashion. The lens cap, with the lens sealed in place, is then placed over the membrane holder and screwed to the manometer tube. Thus a pressure-tight chamber is

B

A

Fig. 3.—Manometer details. Part A, Manometer. MT, Manometer tube; C, collar; LC, cap containing cylindrical lens which is fitted to collar of the manometer.

Part B, Manometer assembly. A, Manometer block. This block contains a circular opening into which the manometer tube fits and allows for rotation of the tube. The tube can be fixed in any desired position by tightening of screw, CS.2.

Part C, Manometer assembly. A, Manometer block; Pl., platform; CS.2, screw for elevation or depression of light beam; pin P which acts as axis for rotation of block A (this axis is parallel to the camera slot); CS.3, screw for rotation of assembly on platform (the axis for this rotation is at right angles to the camera slot).

Part D, Arrangement of manometers.

formed around the membrane. An opening into this chamber allows pressure to be applied to the mirror surface of the membrane, while pressure may be applied to the opposite side through the manometer tube. If the two sides are then connected to the cuff, equal pressures will be applied to both sides of the membrane and no movement will take place. However, a small needle valve is placed in the tube leading to the chamber which enables the rate of pressure change to be controlled so that at any pressure level sudden changes in pressure are not transmitted to the chamber and hence act solely on one side of the membrane. The result is the recording of cuff pulsations at any cuff pressure levels desired.

Fig. 1.

Camera.—The camera is of the usual type and uses 6-inch seismographic recording paper.

Records (Fig. 5).—The types of records obtained by the instrument described are illustrated in Fig. 5, Parts A, B, and C. Fig. 5, Part A, shows the recording of direct arterial pressure (brachial artery) and indirect arterial pressure from the same arm as the cuff pressure is dropped from above to below the systolic level. The time lines are placed across the entire width of this record. In Part B, the time line is placed at the bottom of the record only. This record shows the plethysmographic tracing as well as direct and indirect arterial pressure records and cuff pressure. The recording of venous pressure and respiration is demonstrated in Part C. Here the direct and indirect arterial pressure is recorded as the cuff pressure is decreased from above to below diastolic pressure.

SUMMARY

A new instrument is described for simultaneous recording of intraarterial pressure, pneumatic cuff pulsations and pressure, finger plethysmograph, venous pressure, and respiration. It is easily movable and can be used in well-lighted rooms. The principle is similar to that of the Hamilton manometer.

Fig. 5.—Parts A, B, C. Examples of typical records. CP, Cuff pressure; BL, base line; AP, direct arterial pressure; IDP, indirect arterial pressure; PL, plethysmograph; R, respiration; VP, venous pressure.

formed around the membrane. An opening into this chamber allows pressure to be applied to the mirror surface of the membrane, while pressure may be applied to the opposite side through the manometer tube. If the two sides are then connected to the cuff, equal pressures will be applied to both sides of the membrane and no movement will take place. However, a small needle valve is placed in the tube leading to the chamber which enables the rate of pressure change to be controlled so that at any pressure level sudden changes in pressure are not transmitted to the chamber and hence act solely on one side of the membrane. The result is the recording of cuff pulsations at any cuff pressure levels desired.

Fig. 1.

Camera.—The camera is of the usual type and uses 6-inch seismographic recording paper.

Records (Fig. 5).—The types of records obtained by the instrument described are illustrated in Fig. 5, Parts A, B, and C. Fig. 5, Part A, shows the recording of direct arterial pressure (brachial artery) and indirect arterial pressure from the same arm as the cuff pressure is dropped from above to below the systolic level. The time lines are placed across the entire width of this record. In Part B, the time line is placed at the bottom of the record only. This record shows the plethysmographic tracing as well as direct and indirect arterial pressure records and cuff pressure. The recording of venous pressure and respiration is demonstrated in Part C. Here the direct and indirect arterial pressure is recorded as the cuff pressure is decreased from above to below diastolic pressure.

SUMMARY

A new instrument is described for simultaneous recording of intraarterial pressure, pneumatic cuff pulsations and pressure, finger plethysmograph, venous pressure, and respiration. It is easily movable and can be used in well-lighted rooms. The principle is similar to that of the Hamilton manometer.

A METHOD OF DETERMINING THE SPECIFIC RENAL FUNCTIONS
OF GLOMERULAR FILTRATION, MAXIMAL TUBULAR EXCRETION
(OR REABSORPTION), AND "EFFECTIVE BLOOD FLOW"
USING A SINGLE INJECTION OF A SINGLE SUBSTANCE

MILTON LANDOWNE, M.D., AND ALF S. ALVING, M.D.
CHICAGO, ILL.

METHODS of determining fairly specific renal functions are available at present.¹⁻³ Because of the complications and detail involved, their usage is limited essentially to the field of research. The following attempt at simplification of these procedures has met with partial success and is presented in the interest of a wider clinical application of these newer and more useful renal function tests. No new concepts are involved, but in order to present our method, the underlying principles will be briefly reviewed from our perspective.

A substance which is excreted solely by being filtered through the glomerular membrane appears in the urine at a rate which is directly proportional to its concentration in the plasma water (Fig. 1). Inulin is an example of this type of compound. The ratio of its urinary excretion per minute to its plasma concentration is constant and may be expressed by the slope of the line indicating inulin excretion at varying plasma concentrations. This represents the inulin clearance, or glomerular filtration rate, in cubic centimeters per minute since it expresses the volume of plasma which contains the amount of inulin excreted in one minute. Inasmuch as the excretion of inulin is accomplished only by glomerular filtration, the slope of this line also represents the glomerular filtration rate; that is, the volume of plasma whose water is filtered by the glomerular membrane in one minute.

A substance which is not only filtered, but which also is excreted by the tubules, will have a higher rate of excretion than inulin. If the tubular excretion is proportional to plasma concentration, then the total excretion will likewise be proportional to plasma concentration, and the ratio $\frac{\text{urinary excretion rate}}{\text{plasma concentration}}$ will be constant; that is, the clearance will be constant and greater than the inulin clearance. This is generally true of diodrast in low concentrations (Fig. 2).

As their plasma concentration is increased, certain substances can be delivered to the tubules in quantities sufficient to saturate their tubular excretory

This investigation was aided by grants from Kenneth G. Smith and the Douglas Smith Foundation, University of Chicago, and the Winthrop Chemical Company, Inc., New York, N. Y.

The authors are grateful to Sharp and Dohme, Inc., Philadelphia, Pa., and to the Winthrop Chemical Company, Inc., New York, N. Y., for furnishing the p-amino-hippurate and diodrast used.

Received for publication, May 17, 1947.

Fig. 1.—The excretion of inulin varies directly with its plasma concentration. The slope of this curve, $\frac{uv}{p}$, is constant and represents the plasma clearance of inulin. Since inulin is excreted solely by filtration, the value $\frac{uv}{p}$ measures the rate of glomerular filtrate formation.

Fig. 2.—For diodrast at low plasma concentrations (heavy dashed line), $\frac{(uv)'}{p'}$ is constant and represents the diodrast plasma clearance. Since diodrast is excreted by both glomeruli and tubules, the contribution of each may be found if filtration is determined by simultaneous measurement of the inulin, or similar clearance.
For diodrast at high plasma concentrations, tubular excretion is constant at a maximum (T_m), while glomerular excretion continues to increase with increasing plasma concentration. The total excretion in this range (solid line), therefore, parallels the filtration curve, so that $\frac{\Delta (uv)''}{\Delta p''} = \frac{uv}{p}$ and again measures the glomerular filtration rate.

mechanism. In this case their tubular excretion rate may reach a constant maximum value. The *total* urinary excretion of such substances continues to increase as the plasma level is increased, but only because larger amounts are being filtered. Diodrast, above a plasma total concentration of about 15 mg. per cent, behaves in this fashion and exhibits a constant maximal tubular excretion rate referred to as its T_m (Fig. 2).

These three functions—glomerular filtration rate, diodrast clearance, and maximal diodrast tubular excretion (or T_m)—are usually determined by the simultaneous and sustained administration of inulin and diodrast. It may be readily shown theoretically that these functions can be determined by the use of diodrast alone—inulin being unnecessary for the following reason: Since the curve of urinary diodrast excretion in the range of high plasma levels is a constant distance above the curve of diodrast filtration, the two curves are here linear and parallel, and the slope of the curve for total excretion, therefore, again equals the glomerular filtration rate (Fig. 2). Furthermore, the distance the total excretion curve is above the filtration curve represents the maximum tubular excretion or T_m and can be read on the y axis by extrapolation. Data for these determinations can be obtained by a single intravenous injection rather than by a continuous intravenous infusion.

PLAN OF EXPERIMENTS

Experiments were designed to test the practical validity of this theorem. A single injection of diodrast (or para-amino-hippurate) was given and successive clearance periods obtained as the plasma concentration fell. Inulin was also included in the injection, in order to compare the simultaneous average inulin clearance with the glomerular filtration rate as determined from the curve of diodrast excretion. The following procedure was employed:

Preliminary to, and during, the test a large water intake was provided in order to maintain an adequate, approximately constant urinary flow and extracellular fluid volume. After a blood blank was withdrawn, the substance selected (here diodrast or para-amino-hippurate) was injected intravenously together with inulin in a conveniently small volume of solution. The amounts given were chosen to approximate the desired concentration in a volume of fluid whose mass is equal to 0.25 times body weight. The injection was given conveniently by gravity infusion in five to thirty-five minutes, the rate being controlled to minimize any alterations in blood volume or blood pressure. (Injection of diodrast in less than ten minutes has been noted to produce temporary depression of the diodrast clearance.)

Collection of urine was begun usually twenty-five to forty-five minutes after starting the intravenous injection. Three to twelve (average, seven) urinary samples were obtained, usually successively, each representing periods of nine to forty-six (usually ten to twenty-five) minutes. The usual technique for collection² was followed, using a large indwelling catheter and three successive quick rinsings of the bladder with 20 c.c. of saline, timing the end of rinsing with an accuracy within five to fifteen seconds.

Three or more blood samples were drawn at intervals to establish curves of plasma concentration. Duplicate or triplicate analyses of the heparinized blood plasma and of the diluted urine samples were made in the usual manner.¹⁻³ The plasma concentrations corresponding to two and one-half minutes before the mid-point of each collection period were read from the curve of log plasma concentration plotted against time. In the case of diodrast or para-amino-hippurate, these values were corrected for the water content of plasma and for protein binding, being expressed as milligrams of unbound material per cubic centimeter of plasma water. The average urinary excretion rates corresponding to each of these values were determined by dividing the total excretion of material in milligrams for each period by the length of the period in minutes. The excretion rates were then plotted as ordinates against the plasma concentrations as abscissas.

To all data in the region of maximal tubular function, a straight line was applied by the method of least squares. (This also can be done fairly accurately by inspection.) The selection of points can usually be made if it is remembered that the curve turns toward the origin at low values. The slope of the line obtained represents the average glomerular filtration rate in cubic centimeters per minute, and the extrapolated intercept on the y axis indicates the T_m in milligrams per minute. While this is termed a "graphic" method, the values also can be obtained readily from the formula for the line derived by the method of least squares. (The T_m is the value for y where $x = 0$, and the glomerular filtration rate is $\frac{dy}{dx}$.)

If urinary collections are continued, data may be obtained for low plasma levels. Here the slope of the curve increases to approach a straight line running through the origin. The slope of this line represents the "effective renal plasma flow."

RESULTS

Comparisons have been made in fourteen subjects in the following manner: (1) The glomerular filtration rate (GFR), derived by the aforementioned "graphic" method from diodrast or para-amino-hippurate excretions, was compared with the average of the simultaneous inulin clearance determinations (C_r) for each subject. (2) From the conventional calculations based on simultaneous excretions of diodrast (or PAH) and inulin, T_m 's were obtained, and the average of these T_m 's for each subject was compared with the "graphic" determination of T_m from diodrast (or PAH) excretion values alone. (3) When sufficiently low plasma levels were reached, the graphic and calculated "effective renal blood flow" were compared. (4) In several cases the modified procedure for the "graphic" method followed or preceded the "standard" method of maintaining continuous infusion at approximately constant plasma level, and the consecutive results were compared.

Representative curves are shown in Fig. 3, illustrating variation in grouping of points, self-depression of T_m due to too rapid injection, and clearances at high and low plasma levels of diodrast and PAH. The italicized values are

those calculated from the simultaneous inulin determinations. The comparisons are summarized in Table I. Of special significance are columns 5 and 6 and 10 and 11. Columns 5 and 6 indicate an average difference between methods of determining filtration rate of 8 c.c. per minute or 13 per cent, regardless of sign.

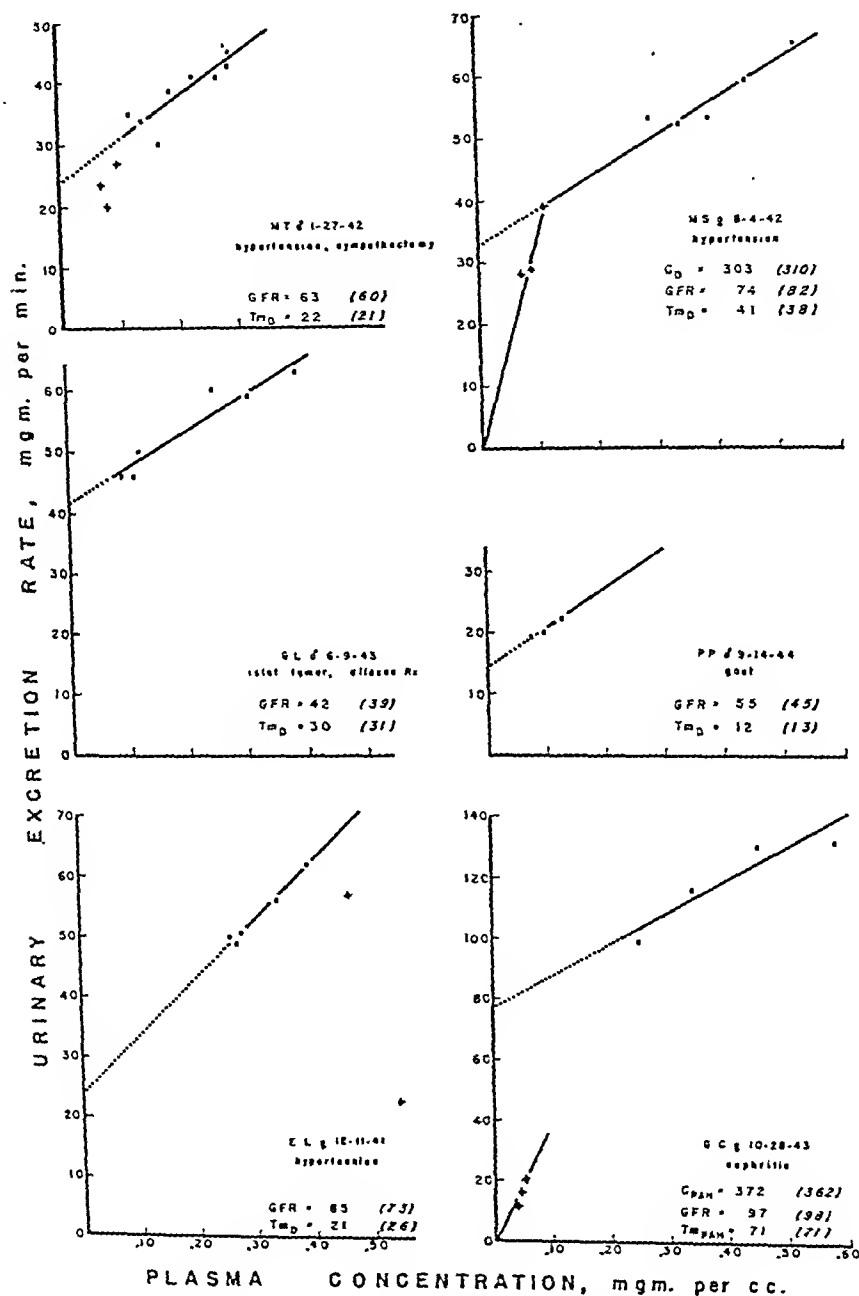

Fig. 3.—Representative experiments showing determination of renal functions by single injection technique. Simultaneous values as determined by standard technique are indicated in italics. (Data indicated as - do not apply to determination of glomerular filtration rate, (GFR) or T_m . Discussed in text.)

*Para-amino-hippurate. All others are diodrast iodine.

†Regardless of sign.

This is to be contrasted with the average of the average deviations for the several inulin clearances in each experiment (column 4), indicating an average variation of 7 per cent in the determinations by the standard method itself. For the Tm comparisons, the average difference between the standard and the simplified method was 3 mg. per minute or 10 per cent, neglecting sign (columns 10 and 11), while by contrast the average of the average deviations of the standard Tm calculations was 6 per cent (column 9). The identity of the averages of the fourteen values for the two methods, both for filtration rates and for Tm, is, in view of the small number of cases, largely a prejudicing coincidence and does not argue for the reliability of the modified method in the individual case.

DISCUSSION

Errors.—This modification shares with all methods of measuring renal excretory function the errors arising from possible misunderstanding of the mode of excretion of the substance being studied, particularly in conditions of disease. Sampling errors are slightly greater than in the standard techniques, because of shorter rinsing, but are probably well within the analytical errors common to both methods.

There are, in addition, three errors introduced by the use of a changing plasma concentration rather than a sustained one. The first is that a representative sample of the mean plasma concentration may not be obtained. If the linear or the logarithmic rate of change of plasma concentration should happen to be constant, then the mean concentration can be read on a suitable graphic plot from the mid-point in time, or calculated from the values at the beginning (P_1) and end (P_2) of the period. Where the plasma concentration fall is linear, the mean concentration is equal to $\frac{P_1 + P_2}{2}$. Where the logarithm of concen-

tration falls in a linear manner (as is the case with inulin and approximately so with diodrast at high plasma levels) the mean concentration is $\frac{P_1 - P_2}{2.302 \log \frac{P_1}{P_2}}$.

For any relationship of plasma concentration and time, the true mean concentration can be arrived at by determining the entire area under the concentration curve for the period, either analytically or planimetrically, and dividing by the length of the period. In forty-two periods a comparison was made of the values as calculated by these three methods: from mid-point in time, by logarithmic plot, and by planimetric measurement. The differences between the values so derived (Table II) did not fall in any consistent direction and were less than the errors inherent in the remainder of the procedure; therefore, the simple "mid-point" value was taken as representative of the mean plasma concentration.

The second error is due to the fact that urine reaching the bladder is derived from plasma a short while previously, and, therefore, does not correspond to the simultaneous plasma concentration. This anachronism is due to

TABLE II. DIFFERENCES IN "MEAN PLASMA CONCENTRATION" AS OBTAINED BY (A) ARITHMETIC MEAN (B) LOGARITHMIC MEAN (C) PLANIMETRIC MEAN VALUES, ALL EXPRESSED AS PER CENT OF VALUE

COMPARISON	AVERAGE DIFFERENCE	MAXIMUM	MINIMUM
A-B	0.5	0.9	-0.8
A-C	0.1	0.6	-0.9
B-C	0.7	1.5	-0.5

a delay in the passage of urine through the kidney and ureters to the bladder, which is relatively greater than the circulatory delay in the passage of blood from the kidney to the arm vein (if venous blood is used). This time lag is variable and was found by Smith and co-workers¹ to average about two and one-half minutes in man. If the plasma concentration is constant no error results, but if the plasma level is rising or falling some correction should be considered. Applying a correction of two and one-half minutes to a curve of falling concentrations produces higher values for mean concentration, and therefore lower clearances, than if no correction were made. Using the conventional method of calculating clearances, but with a falling plasma concentration curve, the average decrease in clearance in thirty-one determinations was 2 per cent (the maximum, 4.3 per cent; the minimum, 0.8 per cent) when a two and one-half minute correction was applied. Conventionally calculating T_{in} from inulin and diodrast excretions based on a falling curve, a two and one-half minute correction resulted in even less change, since the T_{in} is derived by clearance differences. The average correction was -0.8 per cent; the range was from -3.0 per cent to +1.6 per cent. We have therefore applied the correction, concluding that the estimated anachronism of two and one-half minutes can be in error by 100 per cent without introducing significant error in result, except perhaps when very rapid changes in plasma level are occurring.

The third possible source of error arises in case of storage of material by the kidney, to be released during falling plasma concentration. Smith and co-workers¹ have concluded that there is no appreciable storage of inulin or of diodrast since clearances were the same whether obtained when plasma concentrations were rising or falling.

Technique of Test.—An important technical difficulty is presented in obtaining the proper range of blood levels. If renal function is high, or periods too long, too few points may fall within the usable range. On the other hand, if periods are too brief, inaccuracy in urine collection increases; or if renal function is too poor, the change in plasma level may not yield a sufficient scatter of points, unless the test be prolonged unduly. It is therefore imperative that some prior estimate of function be made in each case, as for instance by urea clearance, phenolsulfonphthalein, or concentration tests. When determinations of effective renal blood flow are also desired, it may take some time until sufficiently low plasma concentrations are reached in the case of large subjects, or in subjects with low renal function. In such cases the test may be interrupted and resumed if intermediate points are not desired.

Usefulness of Method.—In determining “effective renal plasma flow,” this method offers an advantage over the standard one in that a check is provided on the constancy of renal extraction at different plasma concentrations. In renal disease the demonstration of a linear relation between excretion and plasma concentration of diodrast (or PAH) may be necessary before the clearance can be considered to represent “effective renal plasma flow.”⁴

Fig. 4.—Various substances exhibiting a maximal tubular transport (T_m), either excretory or reabsorptive, may be used to determine the glomerular filtration rate as well.

By plotting excretion rates against the *total* concentration in the water of the plasma rather than against the concentration of *free* diodrast (or PAH), the T_m value will be unchanged, but the value for glomerular filtration rate will be low by a factor equal to the average per cent of material bound by protein. Smith and associates³ have, in fact, adopted this method to enable them to check the degree of protein binding of PAH.

It is inaccurate to rely upon this method to estimate filtration fractions or to derive other hemodynamic ratios, for not only are the determinations of “effective blood flow” and glomerular filtration not made simultaneously, but the lessened accuracy of the determinations may yield disproportionate inaccuracy in any calculation involving ratios of the values obtained.

The fact that the calculations and analytic detail have been simplified should not suggest that the procedure has achieved true simplicity. We have not had a sufficient experience to predict whether it can be developed to a point where all the pitfalls of the more accurate clearance studies can be consistently avoided.

The method is applicable not only to diodrast, but also to any substance which exhibits a maximal tubular transport, either excretory or reabsorptive (Fig. 4). Data from the literature on hippuran, glucose, and ascorbic acid, when replotted by our method, finds agreement with the original calculations (Table III). Because the analysis of para-amino-hippurate is within the range of many clinical chemical laboratories, this substance is particularly suited to the method. The ideal substance is, however, still to be found, for it must possess the attributes of being nontoxic, not metabolized, not stored, nor rapidly excreted via other routes, must not appreciably or variably be bound to protein, must be readily subject to analysis, and its normal T_m should be large in relation to the error of analysis. With a substance possessing these attributes, a widespread clinical application of this simplified procedure may be feasible.

TABLE III. COMPARISON OF SIMPLIFIED METHOD WITH STANDARD METHOD OF DETERMINING GLOMERULAR FILTRATION AND T_m
(Data from the literature; graph drawn by inspection)

SUB- STANCE	SUBJECT	SIMPLIFIED METHOD		STANDARD METHOD			REFERENCE
		GLOMER- ULAR FILTRA- TION RATE	T_m	CREA- TININE CLEAR- ANCE	INULIN CLEAR- ANCE	T_m

Ascorbic acid	Man (6 experiments)	130	2.5		124.2	2.17	8 (Table I)

Other Simplified Methods.—Other workers have reported on simplifications in the determination of these renal functions. The method of Findley and co-workers,⁹ which assumes that the per cent of injected diodrast excreted in the urine in thirty minutes is a measure of T_m , has no physiologic basis. Applying his method to data determined by standard procedure has yielded errors of several hundred per cent.

Foà and Foà have performed clearances during falling plasma concentrations.¹⁰ Our studies establish the validity of such procedure and offer further simplifications.

Earle and Berliner recently have suggested¹¹ that a sustaining infusion can be given to maintain a constant blood level after equilibrium has been established, when the rate of infusion can be taken to indicate excretion in place of the urinary collections, thus obviating the need of catheterization. How one

establishes the proper level of infusion other than by approximation is not indicated. It is not feasible to perform "spot" blood analyses during the test, and slow drifts in plasma concentration of insignificant degree may be produced by infusions at rates which are considerably different from the rate of urinary loss. For example, an infusion of 20 per cent more inulin than is being excreted will take twenty minutes to increase the plasma concentration by 2 per cent under conditions where plasma level is 100 mg. per cent, the total inulin in the body is 15 Gm., and the rate of excretion is 75 mg. per minute. If extracellular fluid volume remains constant over periods long enough to provide accuracy, then the procedure may have great practicality.

Newman and associates¹² have proposed that the rate of change in plasma level of mannitol after equilibrium has been established can be taken to yield the rate of excretion. We had endeavored to establish this possibility for inulin and diodrast. Disappointingly, we found that the theoretic volume of solution (obtained by dividing the amount of material remaining in the body by its plasma level) continued to rise and did not attain equilibrium during the several hour course of the experiment. Mannitol appears to equilibrate sooner than inulin and/or high concentrations of diodrast, but data establishing the correctness of the assumed equilibration do not appear in the literature. If the volume of distribution could be as reliably known, or held constant, in the case of substances in plasma concentration high enough to exhibit a T_m , then the mathematic derivatives of T_m without urinary collection may become possible. In this method of approach also, a small percentage change in volume of distribution accounts for an amount of test material which is large in proportion to the rate of excretion, especially at high plasma levels.

SUMMARY

Certain specific renal functions may be determined with sufficient accuracy for clinical purposes by blood and urine analyses after a single intravenous injection of one of several substances.

The theoretic implications and the present practical limitations of the method are discussed.

RADIOACTIVE PHOSPHORUS, P³²: A SIX-YEAR CLINICAL EVALUATION OF INTERNAL RADIATION THERAPY

CHARLES A. DOAN, M.D., B. K. WISEMAN, M.D., CLAUDE-STARR WRIGHT, M.D.,^{*}
JOSEPH H. GEYER, M.D., WILLIAM MYERS, PH.D., M.D.,[†] AND
JO W. MYERS, B.S., M.S.
COLUMBUS, OHIO

FOR nearly half a century roentgen radiation has been the most effective palliative treatment for the more chronic leucemic states and allied hematologic dyscrasias, having been first used by Senn in a case of lymphatic leukemia in 1903.¹ There are, however, distinct and obvious limitations in the clinical application of roentgen-ray therapy as well as of radium and other naturally occurring radioactive elements. These have been utilized more or less effectively in medicine by way of external application, but these elements have proved dangerous when deposited within the body as internal therapy. With the development of the cyclotron by Ernest Lawrence, both physicist and biologist were provided with a tool by means of which a wide range of important hitherto stable chemical elements in nature might be rendered temporarily unstable and radioactive for a limited period of time, thus opening up entirely new fields of scientific exploration and control.

In medicine, the diversion of small quantities of selected isotopes essential to normal body metabolism has made possible important tracer element studies, as well as selective internal radiation therapy. Very recently the provision for utilizing the government-owned uranium piles as a source of some of these biologically significant radioactive isotopes is permitting the more rapid development of this field of knowledge through a much greater potential supply of the desired elements.

Of the artificially produced isotopes, radioactive phosphorus (P³²) has been studied most extensively to date as a means of internal radiation therapy. It became evident following the earliest observations in animals that this isotope might be used advantageously in certain human hematologic dyscrasias. Clinical reports evaluating radioactive phosphorus as a therapeutic agent have been made by Low-Beer, Lawrence, and Stone,² Erf, Tuttle, and Lawrence,⁴ Fitz-Hugh and Hodes,⁵ Kenney,⁶ Craver,⁷ Warren,⁸ Hall, Watkins, Hargraves, and Giffin,⁹ Erf,^{10, 11} and Hoster and Doan.¹² Reinhard, Moore, Bierbaum, and Moore¹³ have recently published a comprehensive and detailed summary of the

basic concepts and accumulated clinical experience in this field as a background for the critical analysis of their own observations which renders any repetition of these details at this time unnecessary and inappropriate.

Studies in this laboratory and clinic were initiated in 1941* with radioactive phosphorus from the Radiation Laboratory at Berkeley and were continued with material from the Ohio State University cyclotron when it became functional in 1942. We are now regularly receiving radioactive phosphorus and other isotopes through a government contract from the Manhattan Project, Oak Ridge, Tenn. An analysis of the results to date in our first 100 patients treated with radioactive phosphorus P^{32} is presented in this communication (Table I).

TABLE I. DISEASES TREATED WITH RADIOACTIVE PHOSPHORUS

Polycythemia rubra vera	20
The leucemias

Monocytic	
Acute	9
Chronic	1
Hodgkin's syndrome	16
Metastatic carcinoma and sarcoma	5
Multiplo myeloma	4
Mycosis fungoides	1
Exfoliative dermatitis	1
Total	100

MATERIALS AND METHODS

The base line laboratory studies on all patients included serial complete total white, red blood cell, and platelet counts, white cell differentials using the supravital technique, hemoglobin determinations, reticulocyte percentages, sedimentation rate, and packed cell volume. Repeated bone marrow examinations via sternal aspiration and the supravital technique were made. Determinations of the basal metabolic rate were done routinely, excluding any thyroid dysfunction by the iodine fractionation techniques of Curtis and associates.¹⁴ Appropriate biopsies were performed as the basis for fixed section diagnoses in the carcinomatoses, Hodgkin's syndromes, and mycosis fungoides. Blood volume determinations, using Evans blue dye T-1824,¹⁵ formed a part of the study in patients with polycythemia rubra vera. Complete hematologic studies were made daily in those patients being observed in the University Hospital. Those who were seen as out patients had the same determinations made at intervals of one to eight weeks, depending upon the acuteness or chronicity of the clinical course and the availability of the patient. Certified United States Bureau of Standards Treuener blood cell pipettes were used. The sedimentation rate was estimated by the Wintrobe method as modified for cell volume by Rourke and Ernestine.¹⁶ A modification of the Dameshek method was used for platelet and reticulocyte determinations. Hemoglobin measurements were made by the oxyhemoglobin determinations on the Evelyn photoelectric colorimeter, which was standardized by the Van Slyke apparatus.

Radioactive Phosphorus.—The details of the cyclotron bombardment of the red phosphorus have been adequately considered elsewhere.¹⁷ The phosphorus isotope was converted

*Through the courtesy of Dr. John Lawrence.

into dibasic sodium phosphate by the method described by Kamen.¹³ The route of administration in the earlier studies was determined by the availability and purity of the material. To conserve P^{32} the intravenous route was used most frequently, this being more economical by approximately 30 per cent. The more recent radioactive phosphorus from the uranium piles

Fig. 1.—E. N., 68-year-old white man. Diagnosis: Exfoliative dermatitis of undetermined origin. Normal bone marrow and peripheral blood.

Under P^{32} therapy there was improvement in the skin lesions, with corresponding disappearance of the pruritus. Note the progressive depression and decline in the platelet, erythrocyte, hemoglobin, granulocyte, lymphocyte, and monocyte levels during and after the course of P^{32} . These hematologic changes fortunately re-equilibrated at subclinical levels but serve to warn against the too-free administration of radioactive isotopes where normal hematopoiesis may be primarily concerned.

at Oak Ridge has been supplied as potassium dihydrogen phosphate (KH_2PO_4), and, due to the relatively large amount of potassium, administration has been confined to the oral route.

The Geiger counter has been used in making the measurements of radioactivity.

Phosphorus is selectively deposited in bone and in the nuclei of rapidly multiplying cells. The radioactive and nonradioactive isotopes of phosphorus have identical chemical properties. Thus it is possible for the beta rays emitted by the radioactive phosphorus deposited at these sites to exert maximum inhibitory and destructive effects on adjacent marrow elements. The effect on normal marrow and peripheral blood is illustrated in Fig. 1, data on a patient with resistant exfoliative dermatitis who responded to small doses of radioactive phosphorus with definite but subclinical hematologic side effects.

POLYCYTHEMIA RUBRA VERA

In polycythemia rubra vera there is a characteristic *triune hyperplasia* of all marrow elements—myeloid, erythroid, and megakaryocytic. With the therapeutic means that have been previously employed in this syndrome, including venesection, phenylhydrazine, and various erythrottoxins, adequate control of the hyperplasia of all of the marrow elements has been unsatisfactory.

Fig. 2.—R. S., 73-year-old white woman. Diagnosis: Polycythemia rubra vera.

Venesection during the first four years of observation, while reducing the erythrocyto level, failed completely to control either the white blood cell or the platelet levels which actually rose steadily with accompanying clinical symptoms. The leucemoid picture was promptly to 1941 and again in 1943, and the critical response to P^{32} on each occasion. Since 1941, three complete hematologic and clinical remissions have been induced with P^{32} therapy lasting respectively twelve months, seventeen months, and, currently, seven months. An excellent example of the control of the *triune marrow hyperplasia* with internal radiation therapy.

Fig. 3.—W. R., 60-year-old white man. Diagnosis: Polycythemia rubra vera. During the three months preceding the establishment of the diagnosis in 1942 this patient had both cerebral and coronary thromboses. Venesections and roentgen radiation together failed to maintain a satisfactory hematologic or clinical equilibrium during the next three years. A total of 10.6 mc. P³² administered in small doses over a four-month period induced a remission of one year. Second remission now being induced. Complete relief of the incapacitating vertigo and recurrent intravascular thromboses has been effected. Note the response of the platelets (8,000,000 per cubic millimeter) and granulocytes (26,000 per cubic millimeter) as well as erythrocytes (8,300,000 per cubic millimeter) to this therapy.

This is particularly true of the megakaryocytic hyperplasia and consequent potentially dangerous thromboeytosis. The development at times of hypoprotrombinemia, or the increased viscosity of the blood, plus an elevated level of circulating platelets, makes the opposite extremes of spontaneous hemorrhage or intravascular thrombosis potentially dangerous complications to be anticipated and avoided. When radioactive phosphorus is deposited in bone, the beta radiation is effective in controlling myeloid and megakaryocytic hyperplasia as well as erythroid hyperplasia. With the more effective control of the pan-marrow hyperplasia the incidence of complications is significantly lowered and longevity increased. The experience in this clinic is in agreement with the reports of others, that at the present time properly administered radioactive phosphorus is the therapy of choice for polycythemia rubra vera.

Fig. 4.—R. C., 48-year-old white woman. Diagnosis: Polycythemia rubra vera.

Small token doses of radioactive strontium and phosphorus in 1942 induced suggestive but not prolonged remission in this patient. Subsequent repeated venesections, while controlling the red blood cell and hemoglobin levels fairly satisfactorily, failed to influence favorably leucocyte and platelet levels, which reached 21,000 and 6,127,800 per cubic millimeter, respectively, by April, 1945. With four small divided doses of P³² therapy a remission lasting fifteen months was accomplished, which controlled effectively all marrow elements.

A total of twenty patients with this diagnosis, twelve men and eight women, have been treated in this series (Table II). The ages range from 28 to 73 years. Only two have expired during this period of observation, one from injuries received in an automobile accident and the other from carcinoma of the bladder. Excellent hematologic and clinical remissions lasting from five to nineteen months were effected in ten (Figs. 2 to 4). Seven patients showed partial responses. Four of these required venesection at various times in association with the P^{32} therapy. Two (Cases 7 and 11) had a fall in both white blood cells and platelets to a low normal before the red blood cells had shown a satisfactory response. In both of these instances venesection seemed indicated to bring the red blood cell level to normal since it was feared that further internal radiation therapy might cause a clinically significant granulocytopenia or thrombocytopenia. Thrombocytopenia, neutropenia, and anemia have been noted as complications of P^{32} therapy,¹⁸ and the necessity for careful individualization of dosage cannot be overemphasized. Another case (Case 12) has been seen only at infrequent intervals over the past three years. Only when pruritus became severe was medical attention sought. P^{32} controlled the pruritus satisfactorily. In the limited dosage then available, however, little effect was observed on the hematologic picture. During the earlier years of this study the supply of radioactive phosphorus was very limited, and in the majority of instances where satisfactory remissions were not induced the P^{32} dosage was definitely inadequate. No patient with this diagnosis has developed a true irreversible leucemic, hematologic, or clinical picture in our experience, though a "leucemoid" blood picture has not been unusual.

LYMPHATIC LEUCEMIA

Ten of the eleven patients with chronic lymphatic leucemia (Table III) treated with P^{32} have expired. One is still under therapy (Fig. 5). Excellent clinical and hematologic improvement was obtained in three patients, one of whom (Fig. 6) had developed a marked hypersensitivity to roentgen radiation. Only moderate improvement was effected in three cases and slight improvement in two. In three patients no change in either clinical or hematologic status was apparent; two of these previously had become resistant to roentgen radiation. Three patients with intractable pruritus associated with leucemia cutis were relieved with P^{32} therapy, one of these having received no relief previously from spray roentgen radiation.

LEUCOSARCOMA

(LYMPHOSARCOMA CELL LEUCEMIA)

Fifteen of the eighteen patients with leucosarcoma treated in this series were children under 9 years of age (Table IV). In twelve cases temporary remissions, both clinical and hematologic, were induced, lasting from three days to three weeks; however, the leucemic process then became more resistant to radiation therapy and occasionally appeared actually to be accentuated (Fig. 7). All of these patients have expired.

Fig. 5.—W. C., 55-year-old white man. Diagnosis: Chronic lymphatic leucemia.

Radioactive phosphorus reduced the white blood cells from 90,000 to 20,000 with a reciprocal rise in the circulating red blood cells and hemoglobin levels; the patient was asymptomatic for a sixteen-month period from November, 1944, to March, 1946, on this regime. Then there suddenly developed a subacute erythroclastic crisis with clinical jaundice and a rapid fall in red cells and hemoglobin during a three-week period. The reticulocytes became moderately elevated (6 to 11 per cent). The spleen increased rapidly in size but there was no corresponding enlargement of any of the regional lymph nodes, and the peripheral white cell and lymphocyte equilibrium showed no significant qualitative or quantitative alterations. The bone marrow revealed a W.B.C.:R.B.C. ratio of 2:1 with 60 per cent small mature lymphocytes present, but there was striking evidence of normoblastic and erythroblastic overcompensatory hyperplasia. There was no sign of excessive destruction of marrow elements by the radioactive phosphorus. The adrenalin test further supported a diagnosis of hypersplenism, and splenectomy was advised. Following splenectomy clinical and hematologic equilibrium was promptly re-established. This is an unquestionable example of secondary hypersplenism developing during the course of chronic lymphatic leucemia but unassociated with any generalized constitutional leucemic exacerbation. The remission continues with complete clinical recovery and return to full occupation as of June 1, 1947.

MYELOGENOUS LEUCEMIA

Fourteen patients with myelogenous leucemia have been treated with radioactive phosphorus (Table V). All were chronically ill from a clinical and hematologic point of view except one, a patient with an acute basophile granulocyte leucemia. The criteria for dosage included not only the maintenance of a satisfactory total white blood count, but also of adequate erythrocyte and hemoglobin levels. These latter objectives were satisfactorily accomplished in most instances.

Control of the splenomegaly in these patients proved to be much more difficult than the lowering of the peripheral white cell count (Fig. 8). Frequently roentgen radiation over the spleen had to be invoked to relieve the symptoms referable to the mechanical discomfort occasioned by the massive enlargement of this organ. More intensive P³² therapy was contraindicated because of peripheral blood and bone marrow findings.

In this limited series of cases of myelogenous leucemia, radioactive phosphorus has not proved to be as effective a therapeutic agent on the whole as roentgen radiation (Fig. 9). It is, however, a very useful therapeutic agent in those

Fig. 6.—C. C., 57-year-old white man. Diagnosis: 1. Chronic lymphatic leucemia and 2. carcinoma of the lower bowel.

Medical attention was sought first by this patient for a lower bowel obstruction. Carcinoma of the sigmoid was diagnosed on biopsy. Coexistent lymphatic leucemia was found.

The leucemic process was brought under excellent control with radioactive phosphorus therapy, the white blood count, red cell count, and platelets being maintained near normal values. The carcinomatosis progressed and was the cause of death. At the time of death the leucemic process was under excellent control.

Fig. 7.—N. B., 3-year-old white girl. Diagnosis: Leucosarcoma.

With 7 mc. of radioactive phosphorus over a four-day period there was a precipitous drop in the white blood count from a high of 966,000 per cubic millimeter to 5,000, with a marked regression of the generalized lymphadenopathy and splenomegaly. This clinical and hematologic remission lasted only three weeks. The second course of P₃₂ therapy failed to have any clinical or hematologic effect.

patients who develop an intolerance to roentgen radiation, with intractable and incapacitating constitutional reactions to even very small dosages, as was the case in three patients in this series.

MONOCYTIC LEUCEMIA

Eight of the nine patients with monocytic leucemia treated in this series were clinically acutely ill (Table VI). In the one chronically ill patient, mod-

Fig. 8.—A. W., 63-year-old white woman. Diagnosis: Chronic myelogenous leucemia.

The myelogenous leucemia in this patient responded initially to roentgen radiation with prompt reduction in the splenomegaly; however, she experienced severe radiation sickness following each treatment. A six-month trial of Fowler's solution failed to accomplish satisfactory results within the tolerance of the patient for arsenic. P^{32} was then instituted without any chemical reactions. The peripheral hematologic picture was quickly and adequately controlled. The splenomegaly, which was the source of most of the subjective complaints, continued to progress and became chiefly responsible for the terminal intestinal obstruction.

erate clinical improvement followed the use of P^{32} over a twenty-one-month period. In only three instances was a temporary favorable effect induced in those acutely ill, lasting from two to four weeks (Fig. 10).

HODGKIN'S DISEASE

Eleven of the sixteen patients with Hodgkin's syndrome treated with radioactive phosphorus in this clinic have been reported previously by Hoster and Doan.¹² In none of these was significant benefit from this form of therapy noted. There were several instances in which a dangerous depression in thrombocytes, erythrocytes, and leucocytes occurred incidental to the P^{32} therapy.

Fig. 9.—Comparative effectiveness of (I) external roentgen irradiation, (II) internal radiation with P^{32} , and (III) oral urethane chemotherapy in three patients with chronic myelogenous leucemia. Both spleen size and excessive circulating white blood cells were controlled most effectively by roentgen irradiation; the remission in this patient is continuing after six months. P^{32} reduced the elevated white count but had no effect on the splenomegaly. Urethane produced a transient clinical remission with a fall in the total circulating white cells and rapid decrease in size of the spleen. Upon discontinuing the daily urethane dosage there was an immediate rise in white count with concurrent re-enlargement of the spleen.

MISCELLANEOUS

A small group of patients (four with multiple myeloma, five having malignancies with metastases to bone, one with exfoliative dermatitis of undetermined etiology, and one with mycosis fungoides, Table VII) may be evaluated together. In the patients with malignancies involving bone, temporary relief from pain was obtained, lasting from two weeks to six months; however, no appreciable regression in the lesions could be recognized roentgenologically or clinically.

The cutaneous lesions, associated with a marked pruritus in one patient with exfoliative dermatitis, were significantly improved under P^{32} therapy; however, the bone marrow, which had been normal at the time therapy was started in this patient, reflected the depressant effect of the radioactivity and provided

J.W. Aged 32 yrs. ♂

ACUTE MONOCYTIC LEUKEMIA

Fig. 10.—Following 6 mc. of P^{32} there was a fall in the white blood count from 253,000 to 88,000, during which regression it was still necessary to support the patient with repeated blood transfusions, and neither circulating reticulocytes nor platelets nor granulocytes reflected any regression in marrow invasion by monoblasts. The efficacy of any specific therapy under such circumstances is, of course, very questionable.

the chief criterion upon which the dosage tolerance was established. The patient with mycosis fungoides was under observation for two months. The course was steadily downhill, and he expired without receiving any apparent benefit from therapy.

Aside from the temporary relief of bone pain and pruritus, it is felt that the phosphorus radioactive isotope therapy had no significant effect on the course of the disease in any of these patients.

CONCLUSIONS

1. Radioactive phosphorus has been, in this clinic to date, of greatest value in controlling the clinical and hematologic manifestations of polycythemia rubra vera.

2. P^{32} is a valuable adjunct to other therapy in certain of the more chronic leucemic states, particularly in those patients intolerant of or resistant to roentgen radiation. The splenomegaly in chronic myeloid leucemia has frequently proved more resistant to P^{32} than to deep x-ray therapy.

3. Although internal radiation therapy may cause an occasional brief favorable effect in the acute leucemias, all too frequently P^{32} has appeared to accentuate the clinical acuteness of the leucemic process and has never proved permanently beneficial in our hands.

4. Radioactive phosphorus has failed effectively to control Hodgkin's syndrome in our clinic and may threaten the integrity of the marrow unless great care and discretion are observed in the dosages used.

5. The deep bone pain which characterizes metastatic malignancies to bone may be relieved by P^{32} . The evidence as to specific retardation of the lesions remains questionable.

6. Pruritus secondary to leucemia cutis, polycythemia rubra vera, and exfoliative dermatitis has been effectively controlled by radioactive phosphorus therapy in selected instances.

7. Our source of radioactive phosphorus until recently has been the University of California (Berkeley) and Ohio State University cyclotrons. The supply of isotopes has been correspondingly limited. The recent decision to release radioactive phosphorus, as well as other radioactive isotopes, from the uranium piles of the Manhattan Project for medical and biologic use will make this form of internal radiation much more readily available to clinical investigators. *It must be emphasized that the efficacy of this therapy depends upon "selective" cell destruction. There is a wide variance in individual susceptibility and tissue response. Extreme care in administering internal radiation therapy is therefore essential. Dosage must be carefully adjusted to each patient's needs and to his idiosyncrasies as determined individually. Our experience suggests small, well-spaced doses of radioactive phosphorus with frequent, careful, complete blood and bone marrow studies to insure the integrity of normal hemato-poiesis during this treatment of human diseases.*

				(2) 7.3	21.4	14,950	648,560	5.85	15.4	9,000	308,000		Moderate resistance to P ₃₂ therapy; venesections totaling 5,000 c.c. necessary to maintain equilibrium in addition to frequent P ₃₂ administration
11	E. S.		57, W., F.	6.5	12.9	10,900	5,226,900	3.9	11.5	4,850	213,600	+	Two years of venesections totaled 9,220 c.c. before institution P ₃₂ —650 c.c. during therapy; note platelet response particularly
12	R. W.		40, W., M.	7.18	15.4	29,000	1,959,000	7.4	16.6	26,000	1,240,000	+++	Seen at very infrequent intervals; principal complaint was pruritus; small dosage P ₃₂ would control this symptom satisfactorily for 2- to 4-month periods; hematologic studies too infrequent to evaluate effect on bone marrow; R.B.C. never over 7½ million; a relatively mild trait
13	J. H.		58, W., M.	7.8	11.0	45,000	1,884,000	6.0	8.9	12,500	593,140	+++	Patient expired from carcinoma of bladder; R.B.C., W.B.C., and platelets responded satisfactorily
14	A. K.		33	6.9	11.3	26,500	6,950,000	4.3	9.9	10,100	489,600	++++	P ₃₂ instituted after development of intolerance to phenylhydrazine therapy after two years. After a 5-month remission had thrombosis of gastric vessels; remission for 1 year

[illegible]

TABLE III. RADIOACTIVE PHOSPHORUS THERAPY IN CHRONIC LYMPHATIC LEUCEMIA

CASE	PATIENT	AGE, RACE, AND SEX	ONSET OF THERAPY					ESTIMATED DURATION OF DISEASE BEFORE P ₃₂ THERAPY	DURATION OF DISEASE AFTER P ₃₂ THERAPY	P ₃₂ DOSAGE (MC.)	REMARKS
			W.B.C. (PER C.MM.)	PER CENT OF LYMPHO-CYTES	R.B.C. (PER C.MM.)	HEMOGLOBIN (GM. %)	PLATELETS (PER C.MM.)				
1	L. R.	57, W., M.	93,000	92	2.2	9.0	150,480	6 mo.	3 wk.	3.5 (o) over 14 days	Developed herpes zoster resistant to roentgen radiation during terminal phase; P ₃₂ therapy effected symptomatic improvement; no significant hematologic effect
2	T. K.	54, W., M.	132,000	91	2.9	11.3	467,900	1 yr.	4 mo.	9.5 I.V. over 6 wk.	Lymphadenopathy and splenomegaly diminished significantly; W.B.C. 4 mo. later, 9,150 (with 77% lymphocytes); R.B.C., 1,980,000; platelets, 166,000; expired 2 weeks later
3	H. W.	53, W., M.	162,000	89	5.1	12.8	245,760	2½ yr.	1½ yr.	15.8 I.V. over 12 mo. period	Slight diminution in lymphadenopathy; total W.B.C. ranged from 80 to 100,000 while on therapy; R.B.C., 3,300,000 to 4,600,000; hemoglobin, 9.2 to 11.6; pruritis of leucemia cutis adequately controlled
4	G. V.	63, W., M.	3,500	42	3.1	10.2	161,200	2 yr.	7 mo.	4 I.V.	Resistant to roentgen radiation; pruritis of leucemia cutis relieved with P ₃₂ therapy; lymphadenopathy decreased; no change in hematologic picture except progressive anemia to terminus
5	A. F.	53, W., M.	4,250	50	2.9	8.8	69,840	2 yr.	9 mo.	2.7 I.V. over 4 mo.	Coleman type; roentgen radiation fast; no significant hematologic or clinical improvement; progressive downhill course
6	G. W.	65, W., M.	126,000	94	3.48	8.1	313,200	?	1 yr.	3 I.V.	Resistant to roentgen radiation; P ₃₂ had no significant results

7	B. C.	10, W., M.	136,000	93	37	10.7	131,280	7	5 yr.	17 I.V. over 3 mo. period	Received courses of P^{32} therapy in 1910 and 1913,* accomplishing satisfactory remission; January to March, 1915, received 17 mc. P^{32} ; lymphadenopathy decreased; June, 1915, W.B.C., 16,000; R.B.C., 2.8; platelets, 5,000; expired Nov. 18, 1915; received only P^{32} over 5 year period
8	C. C.	57, W., M.	82,000	90	31	9.2	379,200	7	1 yr.	9 I.V. over 12 mo.	Diagnosis of carcinoma of sigmoid verified by biopsy, coexistent with chronic lymphatic leucemia; the leucemia held under excellent control with P^{32} therapy; patient died of carcinoma with metastases to liver and lung; 1 week before death, W.B.C., 18,000 (62% lymphocytes); R.B.C., 3.0 (Fig. 6)
9	W. S.	15, W., M.	62,000	82	1.7	15.4	399,810	4 yr.	1 yr.	6 over 8 mo.	Received roentgen radiation for 2 years; substituted; maintained W.B.C. between 15,000-30,000; platelets fell to 28,000; expired following intra-cranial hemorrhage, confirmed by post mortem examination
10	W. C.	55, W., M.	90,000	96	3.3	9.1	93,210	6 mo.	21 mo. (Still under 4 I.V. observation)	6 I.V. over 4 I.V.	P^{32} continues to control leucemic process very satisfactorily; developed severe hemolytic anemia which was corrected with splenectomy (Fig. 5); therapy continued
11	G. A. S.	77, W., M.	12,700	50	1.8	10.9	192,360	10 mo.	9 mo.	1 I.V.	The leucemic process under excellent control with roentgen irradiation; leucemias developed and pruritus was resistant to roentgen irradiation; relieved with P^{32} therapy

*By Dr. John H. Lawrence, University of California

TABLE IV. RADIOACTIVE PHOSPHORUS THERAPY IN LEUCOSARCOMA

CASE	PATIENT	AGE, RACE, AND SEX	ONSET OF THERAPY					ESTIMATED DURATION OF DISEASE BEFORE P ₃₂ THERAPY	DURATION OF DISEASE AFTER P ₃₂ THERAPY	P ₃₂ DOSAGE (MC.)	REMARKS
			W.B.C. (PER C.MM.)	PER CENT OF LYMPHO-BLASTS	R.B.C. (MILLIONS PER C.MM.)	HEMOGLOBIN (GM. %)	PLATELETS (PER C.MM.)				
1	N.B.	3, W., F.	939,000	85	3.2	8.0	259,200	3 wk.	5 wk.	7 over 4 days initially; 6 one mo. later	Reduction in W.B.C., 939,000 to 7,000 with definite improvement clinically; remission lasted 18 days; second elevation of W.B.C. to 485,000 was not effected by second course of P ₃₂ (Fig. 7)
2	N.M.	5, W., F.	11,800	67	1.5	4.6	21,280	?	3 wk.	2	No change noted
3	M.S.	8, W., F.	72,000	94	21	5.2	16,360	8 wk.	6 wk.	4 over 7 days	600 r. units failed to have any appreciable effect on the blood picture; after 10 days P ₃₂ instituted; W.B.C. fell from 200,000 to 11,000 in 10 days; terminal roentgen radiation ineffective; expired following massive gastrointestinal hemorrhage
4	M.B.	2, W., F.	102,000	89	2.6	6.5	183,600	6 wk.	3 wk.	2 (o)	Precipitous fall in W.B.C. from 102,000 to 5,500 in 2 days; continued fall to 200 at terminus; marked cervical adenopathy unaffected; 100 r. units to cervical nodes day before death
5	J.W.	7, W., M.	159,000	70	2.9	9.1	167,440	2 mo.	2 mo.	5 over 5 days	Gradual decline of W.B.C. over 2 weeks to 10,350; excellent clinical and hematologic remission for 4 weeks
6	J.D.	8, W., M.	75,000	88	4.5	12.4	336,608	6 mo.	2 mo.	3	Temporary remission of 4 weeks induced; received roentgen radiation during last 2 weeks of life

TABLE V. RADIOACTIVE PHOSPHORUS THERAPY IN MYELOGENOUS LEUCEMIA

CASE	PA- TIENT	AGE, RACE, AND SEX	ONSET OF THERAPY					ESTI- MATED DURA- TION OF DISEASE BEFORE P ₃₂ THERAPY	DURATION OF DISEASE AFTER P ₃₂ THERAPY	P ₃₂ DOSAGE (MC.)	REMARKS
			W.B.C. (PER C.M.M.)	PER CENT OF MYELO- CYTES	R.B.C. (MIL- LIONS PER C.M.M.)	HEMO- GLOBIN (G.M. %)	PLATE- LETS (PER C.M.M.)				
1	J. D.	46, W, M.	193,000	91 (Baso- philic myelo- cytes)	2.9	7.2	123,060	3 wk.	4 days	4.5 (1 dose)	Diagnosis: Acute basophilic leu- cemia; no improvement clin- ically or hematologically; ex- pired 4 days after therapy; post- mortem examination confirmed clinical impression Received intensive roentgen radia- tion during preceding 2 years which had failed to control the peripheral blood picture or the marked splenomegaly adequate- ly; progressive increase in W. B.C. to terminus; P ₃₂ had no ef- fect on spleen size Peripheral W.B.C. maintained be- tween 3 to 5,000 and R.B.C. 3.5 to 5.0 satisfactorily; spleen failed to diminish in size ade- quately, therefore roentgen radi- ation totaling 800 r. given over the spleen; due to limited sup- ply P ₃₂ , roentgen radiation used entirely for last year of life After three months of P ₃₂ therapy there was a flare-up of an old osteomyelitis of mandible; 400 r. units given over adjacent mod- erate lymphadenopathy; W.B.C. ranged 8 to 20,000; R.B.C. 3.3 to 4.5; hemoglobin 9.2 to 12.5 Gm.; platelets fell to 33,000 terminally; splenomegaly ade- quately controlled
2	E. S.	24, W, M.	474,000	95	2.34	4.7	56,160	2½ yr.	26 days	5 (1 dose)	
3	W. C. W.	35, W, M.	173,000	75	3.5	12.8	653,380	6 mo.	2 yr.	26.6 over 1-year period	
4	E. C.	51, W, M.	70,000	38	3.7	11.4	1,159,740	12 mo.	5 mo.	19 over 5 months	

5	J. J.	36, W., M.	38	2.9	9.1	560,240	15 mo.	5 mo.	Radioactive strontium,		Neither radioactive strontium nor phosphorus had appreciable clinical or hematologic response; roentgen radiation to spleen brought about temporary remission; expired 6 months after onset of therapy
									1.1 over 3 weeks; P ₃₂ 11.5 over 4 weeks	24 over 10 months	
6	R. M.	61, W., F.	25	3.58	7.0	436,760	12 mo.	26 mo.			P ₃₂ therapy maintained a mean W.B.C. of approximately 16,000; R.B.C., 3.8; hemoglobin, 10.5 Gm. for 18 months; splenomegally was principal source of symptoms; roentgen radiation therapy for last 10 months of life
7	C. R.	51, W., F.	43	3.9	10.2	555,220	16 mo.	10 mo.	38 (o) 7 months		Developed hypersensitivity to roentgen radiation after 16 months; W.B.C. not adequately controlled (mean W.B.C. 95,000); R.B.C., 3.5 to 4.6; hemoglobin, 9.8 to 12.3 Gm.; splenomegaly controlled; remission 10 months
8	L. E. T.	33, W., M.	47	4.4	13.0	674,000	3 yr.	10 mo.	8½ over 2½ months		No previous therapy; excellent remission with control of splenomegaly 1 year; W.B.C. 22 to 54,000; R.B.C., 4.2 to 4.6; hemoglobin, 12.5 to 13 Gm.; now requiring second course of therapy
9	G. M.	35, W., M.	54	3.3	6.9	893,700	14 yr.	7 mo.	10 over 7 months		Umbilic effectively to lower W.B.C. below 100,000; no significant effect on splenomegaly; R.B.C., 3 to 4.2; hemoglobin, 6.0 to 10.5 Gm.
10	A. W.	62, W., F.	31	3.6	10.5	796,400	3 yr.	1 yr.	17 over 1 year		Developed severe reactions to roentgen radiations after 2½ years; Fowler's solution (4 months) ineffective; P ₃₂ held satisfactory hematologic remission; W.B.C., 8 to 50,000; R.B.C., 3.2 to 3.9; hemoglobin 8 to 11.4 Gm.; no effect on marked splenomegaly (Fig. 8)

TABLE V—CONT'D

CASE	P.A. TIENT	AGE, RACE, AND SEX	ONSET OF THERAPY				ESTI-MATED DURATION OF DISEASE BEFORE P ₃₂ THERAPY	DURATION OF DISEASE AFTER P ₃₂ THERAPY	P ³² DOSAGE (MC.)	REMARKS
			W.B.C. (PER C.M.M.)	PER CENT OF MYELOCYTES	R.B.C. (MIL-LIONS PER C.M.M.)	HEMO-GLOBIN (GM. %)				
11	M.L.	55, W., F.	297,000	63	2.9	7.7	023,280	3 yr.	Continues 12 over 4 weeks	Reduced W.B.C. to 118,000 in 3 weeks; elevation of R.B.C. from 2.9 to 3.8; hemoglobin, 7.7 to 10.1 Gm.; clinically, little change; roentgen radiation instituted
12	J.B.	41, W., M.	261,000	78	3.9	9.5	435,500	2 yr.	22 mo. 14 over 22 months	P ₃₂ has maintained W.B.C. mean of 75,000 over 22-month period; R.B.C., 4.5, and hemoglobin, 12 Gm., without transfusions; splenomegaly controlled satisfactorily
13	R.M.	49, W., M.	100,000	42	3.0	8.9	1,043,280	3 yr.	24 mo. 37 over 22 months	Developed marked sensitivity to roentgen radiation after 3 years of successful control; P ₃₂ therapy for 22 months has not satisfactorily controlled W.B.C. (averaged 175,000) and splenomegaly; R.B.C. mean 3.0, with 9.1 Gm. of hemoglobin
14	B.R.	52, W., F.	176,000	43	3.7	7.5	677,040	2 yr.	9 mo. 13 over 3 months	Developed marked intolerance to both roentgen and urothano therapy; P ₃₂ gradually reduced W.B.C. with corresponding rise in R.B.C., but splenomegaly not appreciably effected

TABLE VI. RADIOACTIVE PHOSPHORUS THERAPY IN MONOCYTIC LEUKEMIA

CASE	PATIENT	AGE, SEX AND RACE	ONSET OF THERAPY				DURATION OF DISEASE AFTER INSTITUTION OF P ³² THERAPY		REMARKS
			PER CENT OF MONOCYTES	R.B.C. (MILLIONS PER C.M.M.)	HEMOGLOBIN (GM. %)	PLATELETS (PER C.M.M.)			
1	D. M.	68, W, F.	89 (monocytes)	3.05	6.1		21 mo.		A total of 25 mc. (o) over 21-month period effected a moderate improvement clinically; the spleen diminished in size during the first 12 months of therapy; the total W.B.C. was not appreciably altered; there was a slow and progressive rise to a terminal W.B.C. of 284,000 with 97% monoblasts
2	J. F. B.	3, W, M.	. 67 (monoblasts)	4.16	11.9	174,720	6 wk.		2 mc. P ³² orally was followed by a fall in the W.B.C. from 39,550 to 6,100 in 7 days
3	C. H.	5, W, F.	96 (monoblasts)	2.7	6.3	137,160	7 wk.		5 mc. P ³² followed by fall in W.B.C. to 8,600 in 21 days; second injection of 1 1/2 mc. had no appreciable effect on the blood picture
4	A. K.	45, W, F.	45 (monoblasts)	2.8	10.5	40,460	4 mo.		25 mc. P ³² orally over 4-month period failed to achieve any beneficial effect; there was a steady rise to a terminal W.B.C. of 171,000
5	E. G.	61, W, F.	70 (monoblasts)	3.03	11.2	133,320	4 wk.		2 mc. P ³² (I.V.) had no effect over a 4-week observation period
6	E. S.	54, W, M.	81 (monoblasts)	2.5	8.5	15,180	4 days		0.1 mc. radioactive strontium (o) ineffective; steady rise in W.B.C. followed by 4.2 mc. P ³² ; continued rise in W.B.C. to 308,000 and terminus 4 days later
7	R. C.	43, W, F.	12 (monoblasts)	2.97	10.2	118,800	4 days		4.8 mc. P ³² (I.V.) over 2-day period effected no results; steady rise in W.B.C. to 69,000 4 days later
8	A. W.	59, W, M.	95 (monoblasts)	2.1	7.4	42,800	4 wk.		5 mc. P ³² (I.V.); no appreciable change in hematologic picture except progressive anemia and thrombocytopenia; no effect on W.B.C.
9	J. W.	32, W, M.	81 (monoblasts)	3.9	10.5	132,000	12 wk.		6 mc. (over 3 days); lymphadenopathy diminished; fall in W.B.C. from 253,000 to 88,000 in 14 days; W.B.C. 2 1/2 months after therapy 4,100 (Fig. 10)
10	P. C.	38, W, M.	79 (monoblasts)	3.13	8.3	87,000	9 wk.		Received 5 mc. P ³² over six weeks; no significant clinical or hematologic change

TABLE VII. RADIOACTIVE PHOSPHORUS THERAPY IN MISCELLANEOUS DISEASES

CASE	PA- TIENT	AGE, RACE, AND SEX	DIAGNOSIS	P ³² DOSAGE (MC.)	SUBJECTIVE RESULTS	OBJECTIVE RESULTS	HEMATOLOGIC RESULTS
1	C. M. C.	58, W., M.	Carcinoma of prostate (biopsy) with metastasis to cranium, pelvis, lumbar spine,	11 over 3-month period	Excellent transient relief of bone pain	No change roentgenologically	R.B.C. fell from 3.5 to 1.4 million and W.B.C. from 8,600 to 1,850 after 2 months of therapy
2	A. H.	25, W., M.	Astrocytoma of cerebellum with metastasis to spleen, bone marrow	17 over 3½-month period	Temporary relief of bone pain	None	Moderate leucopenia (2,600) developed during therapy
3	J. H.	19, W., M.	Retroperitoneal sarcoma with pulmonary metastasis	5	None	None	None
4	E. N.	68, W., M.	Exfoliative dermatitis	7½ over 4-month period	Pruritus markedly relieved	Dermatitis improved significantly	Moderate diminution of platelets, R.B.C., and granulocytes during therapy (Fig. 1)
5	S. F.	54, W., F.	Multiple myeloma	3 (patient was in terminal state)	None	None	None
6	J. W.	37, W., M.	Multiple myeloma	11.5 over 7-month period	Bone pain satisfactorily controlled for 7 months; roentgen radiation used terminally due to inadequate supply P ₃₂	None	None
7	S. A. L.	48, W., M.	Multiple myeloma	15 (o) over 6-week period	Deep bone pain partially relieved for 7 to 10 days following each administration	None	None
8	L. L. V.	43, W., M.	Mycosis fungoides	5.3 (o) over 6-week period	None—progressive downhill course to terminus 2 months after onset of therapy	None	None
9	E. D.	50, W., F.	Carcinoma of breast with metastasis to vertebrae, ribs, liver, and lungs	5.0	No significant relief from bone pain	None	None
10	C. J.	35, W., M.	Seminoma of testicle with generalized metastasis	5.0	No relief from bone pain	None—no roentgenologic evidence of regression of bone lesions; no regression of subcutaneous nodules	None
11	E. M.	48, W., M.	Multiple myeloma	9.5 over 3 months	Clinical status stationary for 6 months	No change roentgenologically	Transient leucopenia (3,350 per c.mm.) developed during therapy

We are indebted to Dr. John Lawrence, University of California, and to Dr. M. L. Pool, Ohio State University, for making available the radioactive phosphorus used in these studies.

FOLIC ACID IN THE MAINTENANCE OF PERNICIOUS ANEMIA

ROBERT W. HEINLE, M.D., JANET T. DINGLE, M.D., AND

AUSTIN S. WEISBERGER, M.D.

CLEVELAND, OHIO

THE first report on the effect of folic (pteroylglutamic) acid in the treatment of macrocytic anemia appeared in November, 1945.¹ Since then numerous reports describing the results obtained in the treatment of pernicious anemia,² macrocytic anemia of nutritional deficiency,³ sprue,⁴ macrocytic anemia of pregnancy,⁵ and macrocytic anemia of infancy⁶ have appeared. In general, folic acid has been found to cause a hematologic improvement similar to or identical with that of liver extracts when given to patients with macrocytic anemia in relapse, as judged by the response of the reticulocytes, erythrocytes, white cells, and platelets. In sprue, in addition, there is a rapid subsidence of diarrhea and a marked improvement in intestinal absorption. One author, however, after study of a series of cases of pernicious anemia,⁷ has concluded that folic acid does not produce as great a reticulocyte response or as complete return to normal of erythrocytes as occurs with liver extracts. Further, he concluded that a combination of liver extract and folic acid is more effective than either alone. These latter conclusions were based upon the observation that reticulocyte response to the combined therapy was greater than might have been expected in some of the cases and the increase in erythrocytes was somewhat more rapid than occurred with either alone. This study compared results obtained in different patients, rather than in the same patient, using as the basis for comparison successive periods of treatment with folic acid, with liver extract, and with a combination of the two. Because of the well-known variation of response in different patients, the validity of comparisons made in different individuals is doubtful, unless the number of comparisons made was sufficient to permit statistical evaluation.

Neurologic relapse has been observed during therapy with folic acid in patients with pernicious anemia, even when the blood was well maintained at normal levels and in the absence of macrocytosis.⁸⁻⁹

The study reported here was undertaken to determine the effectiveness of synthetic folic acid (pteroylglutamic acid)* in maintenance therapy of pernicious and allied macrocytic anemia, and an attempt has been made to compare such treatment with liver extract therapy.

I. MATERIAL AND METHODS

The study included 41 patients with proved macrocytic anemia. In 35, the results of folic acid therapy were compared with previous antipernicious anemia therapy with intra-

From the Departments of Medicine and Pharmacology, Western Reserve University School of Medicine, the Lakeside Hospital, and City Hospital.

This report is part of a study of folic acid aided by a grant from the United States Public Health Service.

Received for publication, May 16, 1947.

*Folic acid was supplied in the form of Folvite by the Lederle Laboratories Division of the American Cyanamid Company, Pearl River, N. Y.

muscular injections of crude and purified liver extracts, oral liver-stomach therapy (Extralin, Lilly) and stomach therapy (Ventriculin, Parke, Davis & Co.). Folic acid therapy was given to 6 patients who were in severe hematologic relapse.

The folic acid was administered parenterally to 25 patients and orally to 16 patients. The intramuscular route was used for all parenteral injections, except in one patient, who insisted upon intravenous administration. The parenteral dose was 50 mg. in 15 patients and 150 mg. in 9 patients. Intervals between injections of from two to six weeks were employed, although the usual interval was either three or four weeks. The duration of this interval was determined, whenever possible, by the previous intervals between injections of liver extract.

When given orally, folic acid was administered in daily doses of 10 to 40 mg.; the usual dose was either 10 or 20 milligrams. No patient in this series was treated with a daily oral dose of less than 10 milligrams.

There were 22 women and 19 men in the series; of these, 33 were white and 8 were Negro. The age of the patients ranged from 37 to 82 years, the average age being 62.4 years. Three patients developed macrocytic anemia following gastric resection and one patient had macrocytic anemia in association with syphilitic fibrosis of the stomach. The others were well-substantiated cases of Addisonian pernicious anemia, as evidenced by the presence of macrocytic anemia, histamine-fast achlorhydria, response to liver extracts or stomach concentrate and, in some cases, the presence of combined system disease and megaloblastic hyperplasia of the bone marrow.

The incidence of degenerative diseases was high, as would be expected in a group of patients in this age range. In addition, 5 patients had syphilis and 2 had diabetes; 3 had had gastric resection, 2 for peptic ulcer and 1 for carcinoma of the stomach.

Because of the errors inherent in the determination of the erythrocyte counts and because the determinations made before the institution of folic acid therapy were performed by different technicians, it was arbitrarily decided that differences in the erythrocyte count of less than 300,000 per cubic millimeter would not be considered significant. A reduction of 300,000 to 500,000 cells per cubic millimeter was considered a moderate decrease; that of 500,000 per cubic millimeter or more was considered a marked decrease. Conversely, an increase of 300,000 cells per cubic millimeter or more was considered evidence of improvement.

In Tables I to IV the values for the erythrocyte count and hemoglobin level prior to folic acid therapy represent the average of many determinations over a long period of time. Values obtained at the end of the period of observation on folic acid therapy represent an average of at least three determinations. Hematocrit values were not regularly determined, either before or after the institution of folic acid therapy. The authors are cognizant of the fact that without hematocrit determinations definite conclusions concerning macrocytosis cannot be drawn.

All the patients were carefully examined, before and during the course of therapy with folic acid, for changes in deep tendon reflexes, diminution of vibratory sensation, astereognosis, muscle coordination, and the presence of positive Babinski and Romberg signs. An attempt was made to evaluate the nutritional status, as judged by weight and evidence of vitamin deficiency (glossitis, cheilosis, stomatitis, gingivitis). The patients were carefully and repeatedly questioned regarding subjective changes in their state of well-being.

II. RESULTS

A. Hematologic Observations.—The patients were divided into two groups: (1) those studied six to twelve months and (2) those studied less than six months.

The first group, consisting of 32 patients, was studied six to twelve months, with an average of 10.7 months. Of these, 23 or 71.9 per cent, were maintained in a satisfactory hematologic state. Eighteen of the 23 (Table I) showed no

significant change in erythrocyte count or in hemoglobin level, in comparison with previous findings obtained following therapy with liver extract; in three cases, improvement was manifested (Table III). One patient (Case 31, Table III) was not in good hematologic remission before institution of folic acid therapy. She was a 51-year-old white woman who was extremely sensitive to substances in liver extract and who had been maintained on nine to fifteen capsules daily of an oral liver-stomach preparation, Extralin B (Lilly), on which therapy normal blood values were not obtained. Another patient (Case 32, Table III) had also been maintained on Extralin B, because of marked sensitivity to intramuscular injections of liver extract, and her erythrocyte count and hemoglobin level were well below normal when folic acid therapy was instituted. Two patients in this group were started on folic acid therapy when in relapse; they had received no liver extract therapy for several months prior to this time (Table IV). These patients showed satisfactory clinical and hematologic improvement.

In 2 of this group of 32 patients a moderate decrease in erythrocyte count occurred, while in 7 a marked decrease developed, as already defined (Table II).

The second group consisted of nine patients studied for one to five months (average, 3.3 months). None of these showed any significant decrease in erythrocyte count. Two showed no appreciable change (Table I) and 3 showed an increase in erythrocyte count, as compared with previous liver extract therapy (Table III). The other four were started on folic acid therapy when in re-

lapse without having had recent previous liver extract therapy (Table IV). A satisfactory hematologic remission ensued in every case. One patient (Case 40, Table IV), at the beginning of treatment, had an erythrocyte count of 340,000 per cubic millimeter; hemoglobin, 1.4 Gm. per 100 ml. of blood; leucocyte count, 1,200 per cubic millimeter; hematocrit, 4.0; mean corpuscular volume, 117.5 cubic microns; mean corpuscular hemoglobin, 41.2 micromicrograms; mean corpuscular hemoglobin concentration, 35 per cent. These values are the average of determination done in triplicate. In our experience they represent the most severe anemia ever seen in pernicious anemia from which the patient recovered.

It should be noted that in the entire series of 41 patients, only 9 had a significant decrease in the erythrocyte count as compared with previous liver

extract therapy (Table II). But, in all these cases, injections were at intervals of three to six weeks; in 5 patients the individual dose was 50 mg., while in the other 4 the dose given was 150 milligrams. The size of the individual dose was not correlated with the severity of the relapse in this group. None of the patients receiving oral therapy had hematologic relapse.

On the other hand, 6 patients of the entire series of 41 showed definite improvement in erythrocyte values as compared with previous liver extract therapy (Table III). Of these, 3 were receiving daily oral medication, 2 were receiving either 45 or 50 mg. at intervals of two weeks, and only 1 was given 50 mg. at intervals greater than two weeks. It should be noted that with the exception of the last patient, those showing improvement were either on daily oral therapy or were receiving intramuscular injection at intervals of two weeks, the shortest period used in this study.

Of the 6 patients showing improvement, 2 (Cases 31 and 32, Table III) had blood levels definitely below normal values at the time of institution of folic acid therapy, while 2 others (Cases 34 and 35, Table III) had blood levels suggestively lower than normal. The improvement obtained with folic acid therapy, therefore, probably indicates that the patients had not been receiving enough liver extracts previously or, as in the case of the patients (Cases 31 and 32), who had been on oral liver extract therapy, were not absorbing the liver extract efficiently enough to maintain normal blood levels.

Of the patients showing hematologic relapse, one case is of particular interest. He was a 59-year-old Italian who had a diagnosis of pernicious anemia established many years before and who had been treated regularly with intramuscular liver extract injections. Recent liver extract therapy had not maintained the blood at normal levels, possibly because of insufficient dosage at insufficiently frequent intervals. When transferred to parenteral folic acid therapy (150 mg. at four-week intervals) there was a further marked drop in erythrocytes and hemoglobin, although the patient stated that he felt well (Fig. 1). He was admitted to the hospital for study, and a reticulocyte count made on the fifth day after the last dose of folic acid revealed a value of 13 per cent

(Fig. 1). Without further treatment the reticulocytosis subsided and there was an increase in red count and hemoglobin. At the end of four weeks, however, the erythrocytes and hemoglobin had again decreased. The rapidity of decrease in the erythrocyte count suggested the presence of a hemolytic process. Determinations of icterus index, serum bilirubin, van den Bergh, and quantitative urine urobilinogen did not support this idea, however. Studies of fecal urobilinogen were not made. It seems likely that each injection of folic

Fig. 1.—Patient (Case 23, Table II) showing hematologic relapse on folic acid therapy, temporary improvement after single injection of folic acid, and improvement after therapy with daily oral doses of folic acid.

acid in this patient caused a characteristic reticulocyte response with increase in erythrocytes and hemoglobin, but this response had ended and the patient had relapsed a little further by the end of each four-week interval. Thus, the course was probably one of alternate responses and relapses, with each relapse carrying the blood values a little lower than before. Such a finding is not surprising in view of our knowledge of folic acid excretion. Steinkamp and co-workers⁹ have shown that a large part of administered folic acid is excreted in a relatively short time. Welch and Heinle¹⁰ have been able to demonstrate little, if any, "storage" of folic acid from study of urinary excretion.

When the patient was placed on oral therapy with folic acid, 10 mg. daily (Fig. 1), there was an improvement in the erythrocyte count to a level maintained when the patient was receiving liver extract. Folic acid, however, like the previous liver extract therapy, was unable to produce a normal erythrocyte count in this patient. Bone marrow studies, including fixed sections of particles obtained by sternal aspiration, did not reveal an unusual amount of fat in the marrow.

Fig. 2.—Patient L. P. 100% hemoglobin=15.6 Gm. per 100 milliliter. Xanth.=xanthopterin. L.E.=Lederle solution of liver extract, 15 units per milliliter. B.T.=Blood transfusion.

Outright failure of response to folic acid has not been reported. One patient observed by us showed very little response to doses of folic acid which have provided a good, if not theoretically maximal, response in all our other patients. This patient was a 46-year-old colored woman with a macrocytic anemia, histamine-fast achlorhydria, and megaloblastic hyperplasia of the bone marrow. During a period of ten days (Fig. 2) she was given daily intramuscular injections of 1 mg. of folic acid with a delayed and very small reticulocyte response (1, Fig. 2). During a second period of eleven days the daily intra-

muscular dose of folic acid was increased to 6 mg. with a second, delayed, very small reticulocyte response (2, Fig. 2). During a third period of twelve days, the daily intramuscular dose of folic acid was increased to 12 mg. with another very small reticulocyte response (3, Fig. 2). During a fourth period of thirteen days the daily intramuscular injections of 12 mg. of folic acid were continued with the addition of daily oral doses of 36 mg. of xanthopterin. A fourth small reticulocyte response (4, Fig. 2) followed. During this entire period of forty-six days there was only a very slight increase in erythrocytes and hemoglobin. She was then given daily intramuscular injections of 15 units of purified liver extract (Lederle, 15 units per milliliter), and on the fifth day after the start of this therapy a theoretically maximal reticulocyte response occurred (5, Fig. 2) and there was a rapid increase in erythrocytes and hemoglobin. The folic acid used in treating this patient was assayed with *Lactobacillus casei* and found to be as potent as labeled. Unfortunately, it was not possible to carry out studies of urinary excretion in this patient.

The reason for failure of response to a dose of folic acid sufficient to produce a good response in all of our other patients is not clear nor is there an obvious explanation for the prompt response to liver extract after failure of folic acid. We have not encountered any other such patients to date, but a similar failure in two patients of Shukers has been referred to by Darby.¹¹

The patient was continued on liver extract therapy for ten months, at the end of which time the erythrocyte count was 4,510,000 per cubic millimeter and the hemoglobin level was 12.6 Gm. per 100 milliliters. At that time she was transferred to folic acid therapy and given daily oral doses of 10 milligrams. During a period of five months on folic acid therapy there has been no significant change in blood values, body weight, or symptoms.

B. General Clinical Observations.—The majority of the patients noted no difference in subjective sense of well-being. The few who did not feel as well were among those receiving intermittent intramuscular injections with decrease in blood values. These patients observed that they felt well for a short time after each injection of folic acid but that the effect did not last as long as with liver extract injections. There were a few patients, particularly those receiving oral medication, who claimed subjective improvement, especially an increase in appetite, after institution of folic acid therapy. No evidence of associated vitamin deficiencies was observed in any of these patients. Body weight was maintained in all cases except in those who showed obvious hematologic relapse.

C. Neurologic Status of Patients.—Neurologic relapse occurred in three of these forty-one patients. The most striking of these has been reported in detail in a previous publication.⁷ The patient, who had addisonian pernicious anemia, was seen in relapse (Case 41, Table IV). Folic acid therapy was begun in daily oral dosage of 10 milligrams. This was followed by a reticulocyte response of 40 per cent (calculated theoretic maximum, 22.3 per cent). There was an excellent rise in erythrocytes and hemoglobin, with complete disappearance of macrocytosis. Eighty-three days after beginning treatment there was a sudden and rapidly progressive onset of paresthesias with rapid loss of deep reflexes and vibratory sensation. At the time of onset of the neurologic relapse, the

blood findings were: erythrocytes, 5,090,000 per cubic millimeter; hemoglobin, 15.9 Gm. per 100 ml.; hematocrit, 48; mean corpuscular volume, 94.5 cubic microns. Vigorous liver extract therapy for twenty-seven days was necessary to produce the first evidence of arrest of the neurologic lesions. Since then the patient has made gradual and steady improvement until there is only a small amount of residual numbness of the fingers and toes. Deep reflexes are still absent and vibratory sensation has not improved. This is in keeping with the concept that degenerative lesions in the spinal cord are not reversible,¹² whereas paresthesias and peripheral neuritis are responsive to therapy.

This patient ate an inadequate diet throughout. At the time of institution of therapy he had only four teeth and this, combined with the naturally poor appetite seen in patients with untreated pernicious anemia, reduced his food intake. Shortly after remission was induced with folic acid he had the four remaining teeth extracted and the resulting sore mouth and complete absence of teeth limited his food intake to liquids for about three weeks. It should be emphasized that after hematologic remission was induced with folic acid the patient had a desire to eat but was restricted from doing so by the absence of teeth.

Another patient (Case 31, Table III) was a 51-year-old white woman with Addisonian pernicious anemia who had developed severe sensitivity to substances in liver extract. After an unsuccessful trial of desensitization, she was placed on oral therapy with Extralin B (Lilly), 9 to 15 capsules daily. This dosage did not maintain the blood at satisfactory levels, and liver extract sensitivity was manifested by a continuous mild skin eruption. She was placed on oral folic acid therapy of 40 mg. daily, reduced gradually to 10 mg. daily. There was a marked improvement in the blood with an associated improvement in sense of well-being. The skin eruption completely disappeared. After a year, however, she developed soreness of the tongue and mouth, without objective changes, and increasing numbness of the feet and hands, the latter especially noticeable since the patient was a seamstress. Therapy with Extralin B was reinstituted at the rate of 6 capsules daily, and folic acid, 40 mg. daily, was given simultaneously. Over a period of weeks the soreness of the mouth disappeared and the numbness of the extremities improved. The skin eruption promptly returned. The patient also probably had inadequate food intake. Her appetite was never robust. She was an extremely "nervous" individual and when emotionally disturbed, which was frequently, she responded with nausea and vomiting so that she would eat little or nothing for two or three days at a time. Repeated x-ray examinations failed to reveal any organic disease of the gastrointestinal tract.

The third patient showing neurologic relapse was a 77-year-old white woman who had been maintained on weekly or biweekly injections of liver extract for many years with satisfactory blood values (Case 34, Table III). This patient also had a poor appetite, with considerable "indigestion," so that she voluntarily limited food intake with respect to both quantity and quality. She was changed to folic acid therapy, 45 mg. intramuscularly every two weeks. After only one month she developed slight but definite increase in numbness of the hands, soreness of the tongue, weight loss, and further decrease in appetite and

increase in "indigestion." She was again placed on intramuscular liver extract therapy (purified liver extract, 15 units per milliliter, Lilly) at weekly intervals and was given a hydrochloric acid-yielding tablet (Acidulin, Lilly) with meals. In a period of days the soreness of the tongue and numbness of the extremities improved and eventually disappeared. Her appetite increased to a degree which astonished her family and she became free of indigestion. Some credit for this improvement, at least as concerns the indigestion, should probably be given to the hydrochloric acid since she is in a better state now than when on liver extract therapy previously, without acid.

All three of the patients who developed evidence of neurologic relapse probably ate inadequately. Whether this contributed to the relapse cannot be stated, but it is not unlikely that inadequate diets may contain an insufficient amount of some substance, other than folie acid, which is able to prevent the onset of neurologic relapse.

D. Patients Sensitive to Liver Extracts.—Folie acid was given to two patients who, because of sensitivity to liver extract, had been maintained on oral medication with liver-stomach (Extralin, Lilly). One of these patients (Case 31) was referred to previously. The other (Case 32), a 77-year-old white woman with addisonian pernicious anemia, also had marked sensitivity to injections of liver extract and was subject to severe bronchial asthma. She had been taking Extralin (Lilly), 9 capsules daily, for several years. On this therapy the erythrocyte and hemoglobin levels (Table III) were not optimal. After institution of folie acid therapy there was considerable rise in the blood values. The patient experienced no subjective improvement, however.

Attempts at desensitization of these two patients were made without success. It has been our experience in general that liver extract sensitivity is apparently an organ sensitivity rather than a species sensitivity, as has been suggested.¹³ It is also not uncommon, in our experience, to find that oral therapy with liver or stomach preparations may fail to maintain adequate blood levels. As demonstrated by the two patients cited, folie acid may well prove to be a valuable form of therapy in such liver extract-sensitive patients. However, in the presence of neurologic manifestations, additional oral liver therapy would be indicated.

III. DISCUSSION

Discussion has begun to appear concerning the relative ability of folie acid and liver extract to produce and maintain hematologic remission. One author, previously cited,⁶ believed that his data indicated that folie acid, unlike liver extract, rarely produced a maximal response in reticulocyte and erythrocyte levels, although he believed a combination of folie acid and liver extract was probably superior to liver extract alone. Another publication,¹⁴ in which the effects of liver extract and folie acid were compared, suggested that the response to folie acid may have been somewhat slower than with liver extract but eventually as good. These authors believed, however, that some patients maintained on folie acid required increasing doses as time elapsed.

In the series of cases studied here, there was no indication that folie acid was unable to produce a maximal reticulocyte response when given in doses of

10 mg. or more daily to patients in relapse, with the one exception cited previously. One patient in particular (Case 41), who later showed neurologic relapse, had a reticulocyte response of 40 per cent when the expected theoretic maximal as calculated for liver extract was 22.3 per cent. This response was followed by an excellent increase in red count and hemoglobin to high normal levels and by disappearance of macrocytosis in a period of sixty-one days.

Similarly, during the period of observation of this group of cases, folic acid showed no inability to maintain the erythrocyte count at high levels when given in sufficient amount. "Sufficient amount" is dictated more by interval than by size of dose. Intermittent medication at intervals of longer than two weeks did not consistently prevent hematologic relapse in these patients. Daily oral administration of 10 mg. was effective in preventing hematologic relapse during the period of observation, which indicates that this method of treatment is the one of choice.

No toxic or allergic manifestations to folic acid have been observed to date except after rapid intravenous administration of large amounts (150 mg. in 7.5 ml. of solution). Several patients so treated responded with vertigo, syncope, and marked drop in blood pressure. Recovery was always complete within two or three minutes, except for a headache, which persisted up to twenty-four hours. Since intravenous medication has no advantage over oral or intramuscular use and since it has the possible disadvantage of even more rapid urinary excretion, there is no indication for intravenous administration. Whether these reactions were due to high concentration of folic acid in the blood or to impurities present in the solution was not determined.

IV. CONCLUSIONS

1. Forty-one patients with pernicious or allied macrocytic anemia were treated with folic acid for periods up to one year.

2. Of these, twenty-six showed no hematologic relapse, nine had a decrease in erythrocyte count, and six showed an improvement when the results were compared with those obtained during previous therapy with liver extract.

3. All nine who developed hematologic relapse were given intermittent intramuscular injection of either 50 or 150 mg. of folic acid at intervals of three or more weeks.

4. Of the six showing hematologic improvement, as compared with previous liver extract therapy, three were given daily oral therapy, two were given intramuscular injections at intervals of two weeks, and only one was given intramuscular therapy at an interval longer than two weeks.

5. Intermittent intramuscular therapy with folic acid at intervals greater than two weeks cannot be relied upon to maintain hematologic remission with individual doses as great as 150 mg. Daily oral medication of 10 mg. did not allow hematologic relapse in any patient observed.

6. Six patients given folic acid while in hematologic relapse had a satisfactory reticulocyte response and increase in erythrocytes and hemoglobin.

7. One patient was encountered who showed very minimal hematologic response when given daily intramuscular injections of 12 mg. of folic acid.

A prompt and theoretically maximal response ensued when liver extract therapy was instituted.

8. Three of the forty-one patients developed neurologic relapse when the erythrocytes and hemoglobin were at normal levels on folie acid therapy. These patients responded to liver extract therapy.

9. In spite of its inability to prevent neurologic relapse, folie acid has a place in the therapy of macrocytic anemia, particularly in those patients who are sensitive to extracts of liver. In such instances, its combination with oral liver extract preparations might be desirable.

10. Toxic or allergic manifestations to folie acid have not been observed except for mild nitritoid reactions following rapid intravenous administration.

11. Because of neurologic relapses occurring in patients treated with folie acid, this drug cannot be considered a complete substitute for liver extract, and liver extract, or liver extract combined with folie acid, must remain the treatment of choice for pernicious anemia.

PERITONEAL IRRIGATION IN THE TREATMENT OF RENAL FAILURE DUE TO TRANSFUSION REACTION

II. ROCKE ROBERTSON, M.D., AND P. S. RUTHERFORD, M.D.
VANCOUVER, B. C.

THE recent report of successful peritoneal irrigation in a patient suffering from renal failure following the administration of sulfathiazole¹ prompted us to use a similar method in the treatment of a man who developed severe renal damage following a transfusion reaction. During the course of peritoneal irrigation, the patient developed generalized edema. Death occurred on the eighth day following transfusion. Because the Tyrode's solution used for irrigation contained a higher concentration of sodium chloride than did plasma, it seems possible that the generalized edema was due to salt retention from the irrigating fluid. Because of the appearance of edema during the course of therapy, this patient is of particular interest.

CASE REPORT

The patient was a white man, 29 years of age, with tuberculosis of the eighth and ninth thoracic vertebrae and a large paravertebral abscess. He was afebrile and the general condition was good. An intravenous pyelogram and repeated urinalyses were normal.

On May 21, 1946, spinal fusion was performed, and during operation a blood transfusion of 500 ml. was given. Cyanosis, unrelieved by oxygen administration, was observed by the anesthetist during and after the transfusion. The total urine output for the following days is shown in Table I.

The oliguria was first noted twenty hours after transfusion and 2,000 ml. of 5 per cent glucose in distilled water and 1,000 ml. of $\frac{1}{6}$ M sodium R lactate were given intravenously. A specimen of venous blood showed no gross evidence of hemolysis and the icterus index was 20. On the supposition that the renal suppression might be reflex in origin, efforts were made to stimulate renal excretion by the intravenous administration of 100 ml. of 25 per cent glucose and 40 ml. of aminophyllin (4.0 Gm.). A high spinal anesthetic and continuous gastric suction were also used. Two days after transfusion the incompatibility of the transfused blood was established. The donor was found to be Group A and the recipient Group O. The patient's blood nonprotein nitrogen gradually became elevated (Fig. 1, Section B) and attained a level of 126 mg. per 100 ml. on May 25 (four days after transfusion). The patient was drowsy, restless, and irritable and the abdomen was distended. Peritoneal irrigation with Tyrode's solution was instituted at 3:00 P.M. on May 25. The following formula was used:

	MG. %
NaCl	800
KCl	20
CaCl ₂	20
MgCl ₂	10
NaH ₂ PO ₄	5
Glucose	100
NaHCO ₃	100

All the ingredients except the sodium bicarbonate were dissolved and autoclaved in 2-liter bottles. The sodium bicarbonate was dissolved and autoclaved separately. The fluid

was warmed in a water bath at 39° C. before being used, at which time the sodium bicarbonate was added together with the following: heparin, 5 mg. per liter; penicillin, 7,500 units per liter; and streptomycin,* 10,000 units per liter. The fluid was admitted to the peritoneal cavity through a mushroom catheter to the left of and above the umbilicus and removed by an abdominal sump suction apparatus directed into the pelvis through an incision in the right lower quadrant. Continuous suction was maintained by a Stedman pump and the suction device was adequate to keep up with any given rate of intake. The greatest rate of flow was 2 liters per hour, the average rate being 1 liter per hour (Fig. 1, Section C). The outgoing fluid was slightly yellowish-green in color and definitely turbid. Peritonitis was guarded against by sterile technique, penicillin dressings around the peritoneal tubes, intramuscular penicillin, and penicillin and streptomycin in the irrigating fluid. The outlet fluid was sterile at all times, and at autopsy there was no evidence of wound infection or peritonitis. The irrigation was maintained continuously except for a lapse of a few minutes on May 27 and for a period of three hours on May 28.

On the morning following the commencement of the irrigation the patient showed considerable subjective improvement. Slight subcutaneous edema of the buttocks and ankles was noted at this time, but the chest was apparently clear. From this time on, the picture was one of slowly progressive generalized edema. Moist râles were heard at the bases of both lungs and on May 27 the patient became dyspneic. On this date a resection with removal of 500 ml. of blood was performed and 150 ml. of twice concentrated plasma were given without apparent effect. The edema progressed and the patient died on May 29, seven days after the administration of the incompatible blood and four days after the institution of peritoneal irrigation.

In addition to the treatment described, the patient received vitamin C and vitamin B complex. Continuous oxygen by B L B mask was given from May 27, and frothy tracheal fluid was repeatedly aspirated. Intravenous fluids were administered as shown in Table II.

During the course of observation the gastric contents were removed through a Levine tube, but this was tolerated only about one-half of the time. While the tube was out the

*The streptomycin was supplied through the courtesy of Dr. L. E. Ranta, Western Division of Connaught Laboratories, Vancouver, B. C.

patient drank small quantities of fluid and vomited intermittently. The blood carbon dioxide combining power of the patient varied between 40 and 66 volumes per cent during the period of observation.

*Autopsy Findings.**—Autopsy revealed the following: (1) acute nephrosis (transfusion kidneys), (2) pulmonary edema (marked), (3) generalized edema, (4) cardiac dilatation, (5) miliary tuberculosis of lungs, liver, and spleen, (6) vertebral tuberculosis and paravertebral abscess, (7) operation (spinal fusion).

The cause of death was pulmonary edema. The abdominal cavity contained about 100 ml. of thin yellowish fluid. There were no fibrinous adhesions over the intestines and the peritoneal surfaces were smooth and glistening. The two abdominal stab wounds were clean and in no place was there evidence of pressure on the viscera by the drainage tubes. The liver weighed 2,200 grams and was large and dark red in color. Its cut surface showed normal architecture. The spleen weighed 450 grams and had old fibrous adhesions at its upper pole. The right kidney weighed 280 grams and the left, 260 grams. They were large but not tense. The cut surfaces revealed pale yellowish-pink cortices measuring 0.6 to 0.7 cm. in thickness. The pyramids were a deeper pink. No petechial hemorrhages were present. The renal pelvises were of normal size and their lining membranes were pale.

The most striking microscopic change in the kidneys was dilatation of all convoluted and straight tubules, with flattening of their epithelium, and the presence of pink-staining fibrillar material in their lumina. Some tubules contained solid, brownish-red amorphous material in this situation. The interstitial tissue in scattered regions was a little loose and edematous and in a few scattered places there was some infiltration with lymphocytes. There was no evidence of renal tuberculosis.

COMMENT

That the irrigation was effective in reducing the blood nonprotein nitrogen is suggested by the large amount of nonprotein nitrogen removed in the drainage fluid (Fig. 1, Section B) which, on May 29, reached a level, in a twelve-hour aliquot specimen, of 110 mg. per 100 ml., and by the decline in blood nonprotein nitrogen following the institution of the irrigation. The blood nonprotein nitrogen reached its lowest level following a period of irrigation at a rate of 2 liters per hour, only to rise again during the time when the irrigation was slowed or temporarily stopped (compare Section B and C in Fig. 1). It seems reasonable to assume that during this four-day period the nonprotein nitrogen would otherwise have risen steadily.

The outstanding feature of the case was the progressive edema and there seems to be no doubt that this was the main factor in causing death. In considering the cause of the edema the following points are important.

Fluid Intake.—The intravenous fluid intake was not excessive (Table II). During eight days of observation the patient received only 6,900 ml., an average of only 860 ml. daily. The oral intake could not be measured accurately enough for record purposes. The patient frequently drank small quantities of water, but also vomited frequently and had a stomach tube (with suction) in place a considerable part of the time. It seems likely that any excess of oral intake over oral output was very small indeed and it may be that the balance was negative.

Fluid Loss.—The respiratory rate was consistently above normal (Fig. 1, Section E) and the patient perspired profusely, causing considerable fluid loss.

*Autopsy performed by Dr. H. K. Fidler, Shaughnessy Hospital, Vancouver, B. C.

The urine output was only 295 ml. in eight days. During this period one enema was given, with good return, and there were three spontaneous and involuntary bowel movements. There was no diarrhea and the stool appeared normal.

Protein Balance.—Protein loss was considerable (Table III) but the effect on the plasma protein was not great.

TABLE III

DATE	PROTEIN CONTENT OF OUTFLOW FLUID	PLASMA PROTEIN
	(GM. PER 100 ML.)	(GM. PER 100 ML.)
5/25/46	0.38	6.2
5/26/46	0.10	5.12
5/27/46	0.06	5.4

Chloride Balance.—On one occasion the patient was given 4.5 Gm. sodium chloride in the form of normal saline. The oral intake was negligible. In spite of this the blood chlorides (expressed as NaCl) showed a progressive rise from 520 to 690 mg. per 100 ml. (Fig. 1, Section A).

In reviewing the foregoing data, it would appear that the edema was not the result of too great a fluid or chloride intake by the intravenous or oral routes. Another possible source of edema-producing fluid was that which flowed through the peritoneal cavity. Its electrolyte content was considerably higher than that of normal blood plasma, and it seems likely that while the nonprotein nitrogenous substances were passing in one direction, electrolytes accompanied by water were passing in the opposite direction and producing hydremia and hyperchloremia.

We can find no other explanation for the rising blood chlorides. In the case reported by Frank, Seligman, and Fine¹ the blood chloride remained high (660 mg. per 100 ml.) and it is noteworthy that pulmonary edema developed in their patient on the third day of irrigation. It may be that if the kidneys had not started to function on the following day, the edema might have progressed. This raises the question as to whether or not Tyrode's solution is ideal.

The normal range of serum chloride (expressed as sodium chloride) is between 570 and 620 mg. per 100 milliliters. The Tyrode's solution used in irrigation contained 800 mg. of sodium chloride per 100 milliliter. Since sodium chloride forms a crystalloidal solution, it would pass readily through the peritoneal membrane until the concentration in the serum approximated the concentration in the peritoneal irrigating fluid.

The assumption that the increased chloride was responsible for the tissue edema is supported by the following passage from Stitt and co-workers:² "One of the major functions of sodium chloride is to maintain the normal osmotic pressure in the body fluids. Some unknown mechanism, in which the kidney must play the major role, keeps the electrolyte content of the plasma nearly constant. . . . If chloride is ingested faster than it can be excreted, it does not accumulate in the plasma but passes (as sodium chloride and water) into the intercellular tissue spaces and produces edema."

In view of the foregoing, it would appear logical to modify the formula of the peritoneal irrigating fluid for future cases so that it contains 570 mg. of sodium chloride rather than 800 mg. per 100 milliliters.

CONCLUSION

In a case of renal failure caused by a blood transfusion reaction peritoneal irrigation with Tyrode's solution produced an apparent beneficial effect on the uremic manifestations, but the patient died because of generalized edema.

The suggestion is made that a modification of Tyrode's solution (reduction chloride content) might prevent such edema.

PERITONEAL IRRIGATION FOR ACUTE RENAL DAMAGE FOLLOWING INCOMPATIBLE BLOOD TRANSFUSION: A DISCUSSION BASED ON THREE CASES

E. E. MUIRHEAD, M.D., A. B. SMALL, M.D., A. E. HALEY, M.D.,
AND J. M. HILL, M.D.
DALLAS, TEXAS

PERITONEAL irrigation as a procedure for clearing waste products from the body has been attempted on several occasions in the past.¹⁻⁴ Recently this procedure has been rejuvenated as a result of improved techniques and results presented by Fine, Seligman and Frank.⁵⁻⁷ Other reports⁸⁻¹⁰ have resulted from the stimulus initiated by these workers.

We have conducted this procedure of peritoneal lavage on three cases of renal insufficiency resulting from incompatible blood transfusion.* Since experience with the first case, there has also been the opportunity to observe the results of different types of management (mentioned later) on additional identical cases and other related types of acute renal damage. The latter will be presented in a review of all known hemolytic transfusion reactions from this hospital since the inception of the blood bank in 1939.¹¹ An appraisal of the peritoneal irrigation technique resulting from this experience seems appropriate.

TECHNIQUE OF PERITONEAL IRRIGATION

Introduction of Inlet Catheter and Outlet Drain.—The arrangement for irrigating the peritoneum has been in each case identical in its main features to that presented by Fine, Seligman, and Frank.^{5,7} Under local anesthesia (novocain) and through a low lateral McBurney incision a "sump" drain^{7,12} (Fig. 1) was inserted into the right lower quadrant and placed in the right paracolic gutter adjacent to the cecum. The incision was sutured snugly about the upper collar of the "sump" drain. Through a minimal skin incision a thoracentesis trocar was introduced through the abdominal wall of the left upper quadrant two inches below the costal margin. A No. 18 French catheter was introduced well into the peritoneal cavity and the trocar was removed. The skin edges were sutured snugly about the catheter. The entire procedure, conducted in the operating room, was completed within thirty to forty-five minutes.

Irrigating Equipment.—The fluid was allowed to enter through the catheter by gravity and was drained out through the "sump" drain into a 20-liter bottle to which slight negative pressure was applied by a Wangenstein suction or a small electric (aspiration) suction pump. On two cases a bacterial Mandler filter was interposed between the entering fluid reservoir and the intake catheter. No additional pressure was necessary for filtration at the desired rate of flow.

Irrigating Solutions.—Mammalian Tyrode's solution as designated by Seligman and co-workers⁶ was most frequently used. On two occasions 5 per cent dextrose in distilled water was deliberately used (see Cases 1 and 2). At other times and for short intervals a sixth-molar sodium lactate and three chlorides (Ringer's) solution was used.

The solutions were prepared in two different manners. In the first case separately sterilized solutions combined prior to utilization were used. In two cases freshly distilled

From William Buchanan Blood Center, Baylor University Hospital, and Southwestern Medical College.

Received for publication, May 27, 1947.

*Two cases in our hospital, one case elsewhere.

water was collected in 20-liter bottles and the previously weighed solid ingredients were added just before use. The latter was much more practical in view of the interposed Mandler bacterial filter.

To each liter of irrigating fluid were added 25,000 units of penicillin and 1 mg. of heparin. During the irrigation, penicillin also was given intramuscularly (usually 20,000 units every three hours). Two cases received streptomycin by peritoneum and muscle during the latter phases of the irrigation.

Fig. 1.—The type of "sump" drain used is represented. The abdominal wall was made to fit snugly about the collar and the wire-mesh portion was placed in the right paracolic gutter.

Once started, the irrigation was continuous in two cases and interrupted by a twelve-hour period in one case. The rate of flow was near 1,000 ml. per hour.

Attempts were made to give a high caloric formula by mouth but were not completely successful. Glucose and amino acid were given, but usually not enough for basal dietary demands. Vitamin B fractions, vitamin C, and calcium gluconate were given parenterally. Multiple transfusions were given for anemia.

CASE REPORTS

Whenever possible, a check on the fluid intake by all portals and on the urine output was maintained. A slight but variable leakage always occurred about the "sump" drain, making the measurement of outflow fluid and total urea recovered

somewhat lower than the true value. The urine urea and chloride content were checked daily in two cases. The blood urea,¹³ chloride¹⁴ and hemoglobin concentration,¹⁵ and the CO₂ combining power of the plasma¹⁶ were checked frequently. Several serum sodium and potassium concentration determinations¹⁷ were made.

CASE 1.—This case has been discussed elsewhere¹⁰ and only essential points will be mentioned. A 36-year-old white woman was given a transfusion for a moderate blood loss anemia. Through a clerical error type A₁, D-positive* blood was given while the patient was of type O, D positive. A severe reaction developed after 175 ml. were given and the transfusion was discontinued.

There was prominent oliguria for twelve days but during the thirteenth, fourteenth, fifteenth, and sixteenth days a steadily increasing urinary output occurred (see Table I). During these sixteen days the fluid intake amounted to some 25,750 ml. (17,000 ml. by vein with 70 Gm. NaCl). There was persistent vomiting. The patient's condition deteriorated markedly. There was azotemia (blood urea, 310 mg. per cent), hypochloremia (blood chlorides, 360 mg. per cent), and acidosis (CO₂ combining power, 40.5 volumes per cent). The following signs developed: gallop rhythm, apical systolic murmur, pericardial friction rub, generalized and subcutaneous edema, clonic muscular spasms, blood pressure, 160/110 mm. Hg, and mental confusion.

Peritoneal irrigation over a period of 5.5 days (sixteenth to twenty-second day) was responsible for the clearance of over 76.84 Gm. of urea from the body.

Despite some apparent improvement during the first three days of irrigation (greater mental clearness, diminished muscular jerks, etc.) the patient became more edematous and the cardiac embarrassment seemed more pronounced.† During this time there was a distinct elevation in the blood chloride and serum sodium concentration but the serum potassium concentration remained normal. The hemoglobin concentration of peripheral blood remained at the same level despite prior transfusions of blood. The acidosis became more pronounced. The blood urea concentration was markedly lowered, a lowering not in keeping with the quantity of recovered urea and, therefore, considered as partly a dilution phenomenon. Vomiting and retching continued. It became quite obvious that notwithstanding an already existing extracellular water-salt overload, water and salts continued to be absorbed from the peritoneal surfaces, thus accentuating an already existing complication.

Dramatic beneficial effects in this case were associated with the washing of the peritoneal surfaces with 5 per cent dextrose in distilled water at this time for a continuous twenty-four-hour period. The recovered solution had a composition of 2.5 per cent dextrose and 0.42 per cent NaCl. By this means alone some 60 to 70 Gm. of NaCl were removed from the body. This correction of the salt overload was concomitantly associated with a copious diuresis. A subsequent transient oliguria developed (partly related to water deficit) which, when corrected, was followed by recovery.

Peritonitis due to *Proteus morgani* was treated with streptomycin. It is regrettable to report the development of vestibular damage which did not become evident until after the patient was discharged from the hospital. Otherwise the patient has recovered.

Comment.—Certain distinct complications occurred during the irrigation period: (1) an accentuation of the extracellular overhydration (pulmonary and subcutaneous edema), (2) an accentuation of the extracellular salt overload, (3) the development of severe acidosis, and (4) peritonitis without gaseous distention. Retching and vomiting continued until the catheter and drain were removed.

In the light of subsequent experience gained with these and related cases since the time of the report of this first case, additional interpretations seem

Peritoneal irrigation was conducted in the interval between the seventeenth to twenty-second day. Notice the recovery of substantial urea, but at the same time a marked decrease in the CO₂ combining power of plasma and a pronounced increase in the blood chloride concentration. The chloride concentration was lowered after the use of the glucose solution as irrigating fluid, but the aldosis persisted. The average normal blood chloride concentration by the method used is 84.5 meq. per liter (or 400 meq. per 100 ml. of NaCl). The fluid intake volume is not completely accurate since at times estimations of the oral intake were made. The tendency was for these figures to be conservative rather than excessive. The intravenous fluid intake was always accurately known. The urine chlorides are listed as grams of NaCl. This is purposely done in order to compare the figures with the grams of urea in the urine. The various abbreviations are self-explanatory.

justified. The usual time interval for kidney regeneration (structural and functional) had already elapsed by the time the irrigation was commenced. Extraneous factors such as the extracellular salt overload seemed to have interfering influences on renal function as reflected by the occurrence of diuresis and recovery when the salt-removing procedure was instigated. Such reasoning suggests that mostly extrarenal rather than truly renal causes were dealt with by the irrigation procedure in this case.

CASE 2.—This patient, a thirty-year-old white woman, had extensive tuberculosis of the right lung for which a thoracoplasty operation (first and second stage) was performed. She was well nourished.

Unmistakable hemolytic transfusion reaction occurred through no fault of anyone concerned. The patient's blood was typed on many occasions and each time was found to be of type A₁, D positive. All donors giving blood to this patient were rechecked and each was found to be of type A₁, D positive.*

	ANTI-C	ANTI-D	ANTI-E	ANTI-C
Patient	+	+	+	+
Donor 1	+	+	—	+
Donor 2	+	+	—	+
Donor 3	—	+	+	+
Donor 4	+	+	—	+
Donor 5	+	+	—	+
Donor 6	+	+	—	+
Donor 7	+	+	—	+
Donor 8	+	+	+	+

Uneventful blood transfusions were given during the first phase thoracoplasty. During and after the second phase operation, two weeks later, transfusions were followed by hemoglobinuria, jaundice, and the typical type of renal insufficiency. Multiple attempts to demonstrate antibodies in the patient's serum (agglutinating, "blocking," and the "third order" types²⁰) were fruitless. The subsequent autopsy demonstrated typical renal lesions of incompatible transfusion type (Figs. 2 and 3).

While under anesthesia (pentothal-cyclopropane-oxygen) during the second phase thoracoplasty the patient received 500 ml. of blood and 500 ml. of 5 per cent dextrose solution. For two hours following the operation the blood pressure remained near 80/60 mm. Hg. Following 500 ml. of dilute plasma the blood pressure became 104/70. At this time (three hours after operation) an additional 500 ml. of blood were given. Nausea and vomiting appeared but the blood pressure remained 114/80. Nine hours after the operation 200 ml. of very dark urine were voided.

Oozing of blood from the operative site began and the blood pressure dropped to 78/50 mm. Hg. After 500 ml. of dilute plasma the blood pressure was 105/70 (nineteen hours after the operation). Under cyclopropane anesthesia the wound was reopened and packed while the patient received 750 ml. of blood, 1,000 ml. of 5 per cent dextrose, and 500 ml. of dilute plasma (blood pressure, from 85/60 to 126/90). At this time 90 ml. of dark brown urine were voided and the patient was distinctly jaundiced (see Table II for icteric index).

The urine specimens during the second twenty-four hours (110 ml.) were likewise brown in color and contained much brownish granular pigment. Because of an alarming lowering of the hemoglobin concentration (5.6 Gm. per cent) the patient was given transfusions on the tenth, eleventh, and twelfth days amounting to 900 milliliters. Again the icteric index was elevated (additional hemolysis).

By summary then, this patient received 2,650 ml. of blood in a twelve-day period, much of which was rapidly hemolyzed through undemonstrated mechanisms.

It was decided to commence peritoneal irrigation as soon as renal insufficiency became definite and severe. We had in mind circumventing advanced renal insufficiency. The total urine volume for a little over three days was 300 to 400 ml., the blood urea concentration was 214 mg. per 100 ml., and, accordingly, the irrigation was initiated.

*The patient's and donors' red cells gave the following results with anti-C, anti-D, anti-E, and anti-c sera of Race.

Peritoneal irrigation was conducted with 5 per cent dextrose in distilled water during the first seven hours as a means of checking the ability of this solution to wash out salts by this technique (refer to Case 1). During this time the solution entered as 5 per cent dextrose and was recovered with the following concentrations: dextrose, 3.9 per cent; chlorides, as NaCl 0.21 per cent; sodium, 91 mg. per 100 ml.; potassium, 8 mg. per 100 milliliters. Thus, in the 5,100 ml. actually recovered at this time the following bulk quantities were measured: 10.7 Gm. of NaCl, 4.64 Gm. of sodium, and 0.4 Gm. of potassium. Additional evidence was gained

Fig. 2.—The gross picture of a kidney from Case 2. The weight was twice normal and the cut surface bulged markedly. The medulla was dusky and striated due mainly to peritubular hyperemia. The cortex was light in color.

that this procedure can wash out substantial salt just as in the Darrow-Yannet experiment.²¹ At the same time some 77 Gm. of dextrose were absorbed.

The irrigation was continued for seven and one-half days. Mammalian Tyrode's solution was used 75 per cent of the time; lactate-Ringer's solution, 14 per cent; and 5 per cent dextrose, 11 per cent. Table II contains the data on this case. The entire amount of urea measured in the outflow fluid was 115 grams. The azotemia abated considerably but again a severe acidosis developed, and some increase in the plasma chloride and sodium concentration occurred.

Most of the 4,025 ml. of fluid given on the first and second days consisted of blood and dilute plasma given to combat blood loss and hypotension. From the third to the eleventh day (irrigation period) the fluid intake, other than by peritoneum, amounted to 13,030 ml. and was given to equalize the insensible water loss and slight urinary output. On this regime

Fig. 3.—Section of kidney shown in Fig. 2. The glomeruli are of normal size and cellularity, but there is protein precipitate within the capsular spaces. The proximal segments are shown in the upper portion and display hyaline droplets in the cytoplasm. The distal segments are lined by thin regenerated epithelium and contain granular hemic casts. In the center damaged epithelium has sloughed into the lumen and surrounds a heme cast (brownish granular) in the manner of a collar.

the patient became edematous in the subcutaneous zone, but there was no demonstrable pulmonary edema. Such circumstances can be explained best by considering that water and salts were absorbed through peritoneal surfaces.

The hypertension which began on the third day persisted throughout the irrigation period. During the first three days sodium bicarbonate was given (1 Gm. every four hours) but this was discontinued when the edema was noticed. Within two days a severe acidosis associated with Kussmaul breathing appeared. In required 32 Gm. of sodium bicarbonate in twenty-four hours to alleviate the acidotic breathing. The acidosis was modified but remained severe.

The same scheme is used as in Table I. The chloride determination was performed on samples of plasma on each occasion. The normal plasma chloride concentration is usually given as 103 meq. per liter. Notice that a prominent hypochloremia existed at the outset of the irrigation.

Acidosis and increase in the chloride concentration are evident. The fluid intake was accurately measured in this case. After cessation of the irrigation the CO₂ combining power was elevated and the chloride concentration dropped once more.

Up to the fourth day of irrigation there was little evidence of improvement other than reflected by a lowering of the blood urea concentration, a minimal increase in urinary volume, and a recession of the jaundice. At this time pronounced hemodilution existed (hemoglobin 5.6 Gm. per cent) and three small (300 ml.) transfusions were given. That this course was unsuccessful was attested by the recrudescence of the jaundice, the subsequent rather fixed oliguria, progressive weakness, and mental confusion. The course continued downhill with marked gaseous distension, and expiration occurred following a convulsion on the fifteenth day.

On the fifth day of irrigation the outflow fluid became cloudy and showed many strands of fibrin and clumps of leucocytes. A culture at this time yielded a growth of a gram-negative bacillus identified as *Protens*. Streptomycin therapy was initiated and continued until the exitus (0.25 Gm. intramuscularly every four hours).

Pertinent features of the autopsy findings are given. There was widespread fibrocaseous tuberculosis of the lungs with nearly complete destruction of the right lung and extensive involvement of the left upper lobe; the left lower lobe constituted the only morphologically intact lobe. Of much interest was the complete absence of evident pulmonary edema. A minimal amount of greenish-yellow fibrinopurulent exudate was found about the catheter and drain wounds but in all other areas the peritoneal surfaces were of normal smooth and glistening appearance. The liver displayed moderate fatty metamorphosis and bile staining. The kidneys were outstanding. They were twice normal in weight (right, 300 grams; left, 300 grams); the cut surfaces bulged prominently; the capsule stripped easily, leaving a smooth surface; the cortex was gray-yellow in color; the medulla was dusky and well striated (Fig. 1). Microscopically the following were noted: protein precipitate in the glomerular capsular spaces, normal-appearing glomeruli, prominent hyaline droplet accumulation in the cytoplasm of the cells lining the proximal segments, focal necrosis of the distal segments with focal inflammatory foci (lymphocytes, eosinophils, macrophages, fibroblasts), many heme casts in the distal segments (brownish granular and eosinophilic granular types), prominent sloughing of damaged cells of the distal segment, regeneration of the distal segment, and interstitial edema. The regenerated distal segments were lined by very flat cells as described by Lucke²² (Fig. 2). Prominent medullary capillary hyperemia was present.

Comment.—This case presented several points of much interest. In the first place the exact antigen-antibody mechanism causing the hemolysis was not demonstrated, but undoubtedly multiple hemolytic transfusion responses occurred and resulted in a severe type of renal insufficiency. The failure to demonstrate any type of antibody (agglutinating, blocking, developing) in the patient's serum, despite daily checks, was a new experience for this center. It could be that the transfusions cleared the serum of antibodies and that the widespread tuberculosis hindered further antibody production.

A series of interesting points were related to the irrigating procedure. It was reasoned that by initiating irrigation early it would be possible to keep ahead of the deleterious aspects of renal insufficiency and to precipitate an early recovery of the kidneys. It is now clearly apparent that this was a distinct mistake. The usual progress of the renal phase was not altered, as can be appreciated by comparing this case with fourteen others discussed elsewhere.¹¹ Considerable urea was cleared from the body, but a severe acidosis developed and generalized edema was a continuous threat. It becomes apparent that the difficulties in this case resembled those of Case 1.

By the foregoing remarks it is not meant to imply that the irrigation procedure necessarily caused the fatality. Two other complications were more likely to have been implicated in this sense: (1) overwhelming pulmonary tuber-

culosis demonstrated at autopsy and (2) repeated transfusions with hemolytic response. But it does appear that the procedure was begun much too early, that the usual course of these cases was not altered, and that certain deleterious complications were once more demonstrated.

Finally, this case offered three other worth-while informative features. (1) The washing out of salts and base via the peritoneum by a nonsalt-containing fluid was again revealed. This is merely a clinical application of the Darrow-Yannet experiment²¹ and is fraught with possible deleterious fluid shifts under certain conditions (see Discussion). (2) The absence of a diffuse peritonitis following seven and one-half days of irrigation when penicillin and streptomycin were used is in itself worthy information. (3) The morphologic renal picture corresponded with the lesions designated by Lucke²² as "lower nephron nephrosis" and included sloughing of damaged tubular epithelium and well advanced regeneration of the same by the fifteenth day.

CASE 3.—This case is that of a colored woman, aged 49 years, who developed a prominent hypotension associated with blood loss during a hysterectomy for multiple leiomyomas.* Due to the urgency of the hypotension, unmatched blood was given (500 ml.).

The blood pressure remained low (70/40 to 86/70) for nearly twenty-four hours. The patient had received 3,500 ml. of blood. A laparotomy revealed a hematoma in the pelvis and the oozing of blood; this was controlled and the blood pressure returned to normal. (Hemorrhagic tendencies are not an infrequent complication of hemolytic reactions.)

On the second day the icteric index was 26. The first urine specimen was dark red. Oliguria became marked (for ten days about 100 ml. daily). There was mounting azotemia, acidosis, and hypochloremia (Table III). Vomiting was troublesome. The patient became comatose and developed muscular twitching. The total amount of fluid intake is not known. During the first five days roughly 3,000 ml. were given in addition to the blood given for the hypotension. Between the fifth and tenth day 13,500 ml. of intravenous fluids were given, of which 5,000 ml. were of isotonic sodium salt composition.

14	106	227		104.7								

*The chloride concentration is once more as blood chloride (average normal, 84.5 meq. per liter). The total fluid intake was not accurately measured or estimated.

Again the drop in CO₂ combining power of plasma and the increase in chloride and sodium concentration during the irrigation are evident.

*This case was observed in another hospital by one of us (A. B. S.). It is not included in the fifteen cases of hemolytic reaction reported separately.¹¹

During the eighth, ninth, and tenth days the stomach was periodically washed for clearance purposes. It is of interest that on two occasions the urea concentration of the aspirated fluid was determined to be 3.4 and 3.2 mg. per 100 milliliters.* During this period there was a slight decrease in the blood urea concentration, but the CO_2 combining power of the plasma was elevated and the hypochloremia became of extreme proportions. The serum sodium concentration was within normal limits.

On the tenth day peritoneal irrigation was started because the patient did not appear to be improving. During the following three days 71.5 Gm. of urea were cleared from the body by this means. The urine volume output was increasing slightly. The blood urea concentration dropped markedly but there was pronounced acidosis (Table III). The blood chloride and serum sodium concentration were prominently elevated. On the fourth day of the irrigation the patient succumbed to an accident not related to the peritoneal irrigation or to the renal insufficiency.† The ultimate outcome of this case, therefore, is not subject to appraisal in so far as the renal lesion and irrigation are concerned.

Comment.—Again peritoneal irrigation was responsible for the clearance of a substantial quantity of urea from the body, but concomitantly a severe acidosis developed and there was once more evidence of the uncontrolled absorption from the peritoneal surfaces (elevated Cl and Na concentrations).

The autopsy findings demonstrated typical renal lesions. There were heme casts and sloughing of the damaged cells of the distal tubule and evidence of regeneration by the fourteenth day. Again no diffuse peritonitis was encountered.

TABLE IV. UREA CONCENTRATION (MG. PER 100 ML.)
BLOOD AND PERITONEAL FLUID

DAY	CASE 1		CASE 2		CASE 3	
	BLOOD	PERIT.	BLOOD	PERIT.	BLOOD	PERIT.
1	310	133.5	214	133	472	176
2	214	103	229	120	389	99.5
3	178	76	217	88.5	269	102.6
4	169	71.2	191	80.2		
5	120	58.4	174	53.4		
6	107	71	165	64.6		
7-8			123	65		

Notice the usual decline in the urea concentration of the peritoneal escape fluid as the blood urea concentration decreased. These concentrations are minor as compared with the normal urine urea concentration.

DISCUSSION

Continuous peritoneal irrigation has been demonstrated again to remove urea from the body. The urea has been used as an index of the clearance of other waste products. The degree of efficiency of this procedure can be appreciated by examining Table IV. The highest urea concentration in the outflow fluid occurred on the first day when the blood urea level was highest.‡ This highest concentration still fell short of the normal urine urea concentration by ten to fifteen times. Extremely large volumes of fluid therefore were necessary in order to clear daily between 15 and 30 Gm. of urea from the body. As the blood urea concentration was lowered there was some correlation with the decrease in the peritoneal fluid concentration.

*At this concentration in order to clear the 30 Gm. of urea removed on the first day of peritoneal irrigation it would have required 1,000,000 ml. of gastric washing fluid.

†While a sternal transfusion was being attempted (hemoglobin, 6.8 Gm. per cent) 3,000 ml. of blood were introduced into the mediastinum and pleural spaces.

‡This feature satisfies the law of partial pressure as applied to osmotic interchanges.

Two major complications were related to the irrigation procedure in each case: (1) a severe acidosis and (2) the absorption of water and salts from the peritoneal surfaces. There were indications that the acidosis was due to the differential washing out of base while neutral salts were absorbed. Generalized edema developed or became accentuated, and the threat of pulmonary edema remained constant.

Peritonitis was demonstrated in each case but was of a focal nature, being localized about the intake catheter and outflow drain. As a result of exudate accumulation about the "sump" drain the recovery of fluid became less and less efficient after the fifth day. Diffuse peritonitis apparently was prevented by penicillin and streptomycin. Gaseous distention was troublesome in one case.

We are familiar with six other cases of peritoneal irrigation for acute renal damage reported in the literature of recent times⁷⁻⁹; four of these cases had renal insufficiency following incompatible blood transfusions. The present group brings the total number to seven. In order to appraise this procedure it becomes necessary to review briefly the sequence of events in such cases.

The clinical course of patients experiencing incompatible blood transfusions may be divided into three phases¹¹: (1) *hemolysis, hypotension, etc.*, is characterized by a sudden onset with apprehension, tightness in the chest, backache, dyspnea, cyanosis, mental confusion, hypotension, chill-fever, and hemoglobinemia-hemoglobinuria. (2) *Renal insufficiency* is attended by oliguria, heme casts in the urine, hypertension, azotemia, altered chemical pattern of blood (mainly depressed serum sodium, calcium, blood chloride concentration, and CO_2 combining power of plasma), and mounting antibody titer. (3) *Copious diuresis* is accompanied by marked water-salt loss from the body. Experience with these and related cases have led us to the conclusion that each phase requires its own distinctive type of management.¹¹ During the first phase, blood transfusion of undoubted compatibility should be given to cope with anemia and lowered blood volume, thus decreasing the period of hypotension. During the second phase, forcing fluids seems deleterious because the kidneys are not in a position to handle water and salts. The best results during this period have been obtained by restricting the fluid intake to a conservative estimated insensible loss plus the scanty urinary output (a total usually of 800 to 1,500 ml. daily for six to eight days). A high calorie-low salt formula has been given with this fluid plus water-soluble vitamins. Sodium bicarbonate (4 to 6 Gm.) has been given daily to cope with an excessive lowering of the CO_2 combining power of plasma. This regime is based on the premise that damaged kidneys require time for healing. When the diuresis appears (eighth to fourteenth day) the water-salt loss through this means is replaced. Such losses may require 20 to 40 Gm. of salts daily plus 5,000 to 10,000 ml. of water. As soon as possible the patient is allowed to adjust his own intake and output.

It has been our experience that patients overloaded with water and salt have expired or the onset of diuresis has been delayed (fourteenth to eighteenth day).

Experience with this three-phase management and with the three cases of peritoneal irrigation has led us to a more critical view of the irrigation procedure. The complications of acidosis and water-salt overload occurring during irriga-

tion seem to be the particular deleterious influences that the outlined three-phase management appears to prevent. With the three-phase management the results have been very encouraging¹¹; with the irrigation procedure the results have been rather discouraging.

The discouraging features of peritoneal irrigation are not confined to our three cases. A study of the protocols of the two cases presented by Fine, Frank, and Seligman⁷ yield evidence of water-salt overload and of no particular shortening of the usual period necessary for recovery. In the case of Reid, Penfold, and Jones⁸ it is difficult to accept the interpretation that the removal of 6.4+ Gm. of urea in two days was an effective means of supporting renal function. Moreover, the onset of the diuresis coincided with the usual time for this phase.

The case of Goodyear and Beard⁹ had a stated daily intravenous fluid intake of 3,000 milliliters. Over a sixteen-day period such a regime alone is conducive to a fluid overload when renal insufficiency exists. The amount of urea recovered in the outflow fluid within a six-day period amounted to about 15 grams. One wonders how influential was the factor of dilution in the displayed drop in nonprotein nitrogen concentration. The diuresis phase, which was delayed in onset, occurred after the irrigation.

While treating a case with azotemia, the ability of hydremia to lower the concentration of nitrogenous waste products must be kept constantly in mind. Otherwise a spurious sense of improvement may be enjoyed when actually a deleterious water and/or salt overload is in progress.

The complications encountered in the three presented cases during irrigation have ensued while crystalloid solutions approaching the composition of plasma (minus proteins) were being used. A fluid of different composition may prevent these complications but of this we are not aware at present. Hypertonicity of the inflow fluid has been conducive to pain in a few brief trials.

The results herein presented indicate the need for an earlier and sustained replacement of base. Perhaps the measurement of total base in the outflow fluid would indicate the necessary replacement. Even so, the prevention of the absorption of neutral salts and water remains an additional major problem.

The use of 5 per cent dextrose in distilled water appeared beneficial in Case 1 by removing salt from the body. After nineteen days the kidneys were regenerated and ready for the diuresis phase of functioning. It must be emphasized, however, that the removal of salt in this manner when the kidneys are not ready to discard water may be attended by deleterious intracellular water shift as pointed out by Darrow and Yannet.²¹

CONCLUSIONS

1. Experience with these patients following incompatible blood transfusion in whom peritoneal irrigation was conducted for the treatment of renal insufficiency according to described techniques has been disappointing. Substantial quantities of urea (and presumably other waste products) were cleared from the body. However, two major complications, accentuation of acidosis and the absorption of water and salts from the peritoneum, seemed related to the use of crystalloid solutions for irrigation. Such complications are considered

deleterious to the progress of these patients during the renal insufficiency phase and may retard the onset of diuresis. In contrast, an outlined "three-phase" regime seems to oppose these particular complications.

2. Diffuse peritonitis was absent in two cases examined post mortem. Presumably penicillin and streptomycin therapy prevented this complication. Vestibular damage was subsequently observed in one case following streptomycin.

3. The data obtained in the cases herein reported appears to agree with those of other cases of incompatible blood transfusion and renal insufficiency which have been subjected to this procedure and reported in the literature. There seems to be disagreement in the interpretation given these data.

SERUM PROTEINS IN ACUTE INFECTIONS

R. S. STACEY, M.A., M.D.
BAGHDAD, IRAQ

AS TURBIDOMETRIC methods for the estimation of proteins in biologic fluids have been shown to be unreliable,¹ they have been discarded except for rough approximations. During an investigation of the causes of error, it was observed that in certain acute infections a turbidometric method gave consistently low results for serum albumin when compared with those given by other methods. In the following, these experiments are described and certain conclusions reached concerning the nature of serum proteins in infection.

METHODS

Fractionation of Serum Proteins.—

1. Howo's² method. The globulin in 0.5 ml. serum was precipitated with 9.5 ml. sodium sulfate (22.2 Gm. per 100 ml.) at 37° C. and separated by filtration.
2. The Aqueous-methanol method of Pillemer and Hutchinson.³ The globulin in 1 ml. serum was precipitated by 4 ml. methanol reagent at 0 to 1° C. and separated by centrifuging or by filtration. The clear solution was diluted to four times its volume with saline.

Protein Estimations.—

1. Macro-Kjeldahl nitrogen estimation.
2. Biuret method. The color, developed by Fiske's⁴ method, was estimated in a photoelectric absorptiometer using a green filter (wave length 525 mμ). The instrument was calibrated from the results of parallel Kjeldahl estimations.

Turbidity Methods.—

1. Total serum protein. One milliliter serum was diluted to 100 ml. with saline (0.9 Gm. per 100 ml.). To 1 ml. of this solution 1 ml. water and 3 ml. sulfosalicylic acid (5 Gm. per 100 ml.) were added.
2. Serum albumin. To 0.5 ml. albumin solution (Howe's filtrate or diluted methanol filtrate), 1.5 ml. water and 3 ml. sulfosalicylic acid solution were added. When the serum albumin was high, the filtrate containing the albumin was first diluted with an equal volume of the solution used for precipitation.
3. For the determination of the specific turbidity (discussed later) of serum globulin the precipitated globulin was washed twice with the precipitant used, dissolved in saline or weak soda, made up to twenty times the original volume of serum, and the protein content and sulfosalicylic acid turbidity estimated. For the latter, 0.5 ml. solution was taken and the precipitation completed as in the case of albumin.

The sulfosalicylic acid was always added slowly, with constant shaking, and the turbid solutions allowed to stand in the incubator for thirty minutes at 37° C. After thorough mixing the optical density of the suspensions was estimated with a photoelectric absorptiometer which had been calibrated with a standard suspension of formazine.⁵ This was prepared by mixing 14.5 ml. hexamino solution (10 Gm. per 100 ml.) with 14.5 ml. hydrazine sulfate solution (1 Gm. per 100 ml.) and, after forty-eight hours, diluting to 200 ml. with water. The optical densities of dilutions of this suspension were determined in the absorptiometer, and a curve was constructed from which protein turbidity could be read in terms

From the Royal Faculty of Medicine.
Received for publication, May 19, 1947.

of the standard formazine solution taken as 100. The result was multiplied by a factor depending on the amount of serum present in the aliquot used, so that the final figure represented the turbidity produced in a volume of 5 ml. by 1 ml. of 1 per cent solution of the original serum (total protein, 1; albumin, 0.4, if 0.5 ml. albumin filtrate had been used; globulin, 0.4). For all results recorded here a green filter was used (525 $m\mu$ wave length).

As there are not large differences between the quantities of protein precipitated on each occasion, a comparable figure may be obtained for each protein by dividing the turbidity figure by the percentage of that protein in the serum. This figure will be referred to as the "specific turbidity" of the protein.

EXPERIMENTS WITH HOWE'S METHOD OF FRACTIONATION OF SERUM PROTEINS

Sera from normal subjects and from patients with acute infections were fractionated and the total protein, albumin, and globulin determined by the biuret method. The turbidity produced in these fractions by sulfosalicylic acid was measured and the specific turbidity of each protein calculated. In a number of cases serum protein values determined by Kjeldahl were used; these always gave similar results.

Results.—From Table I it can be seen that in acute infections the specific turbidity of total protein and of albumin is reduced, the reduction being small in the case of total protein, large in the case of albumin. During convalescence the value of the latter returns toward normal.

The specific turbidity of globulin in normal persons and in patients with acute infection is given in Table II. It is low and nearly constant and shows no change parallel to that of the albumin. This suggests that the reduction in the specific turbidity of the total protein and the much greater reduction in that of the albumin is to be sought in a change in the albumin-sulfosalicylic acid precipitate. Such a change might be chemical and/or physical; if physical, it might be brought about by the presence of some substance in the albumin filtrate.

In a number of cases the albumin in the filtrate was precipitated by 9 volumes of hot acetone-ethanol (50:50), centrifuged, the supernatant fluid poured off, and the precipitate, after being drained, dissolved in weak caustic soda solution. The turbidity produced by sulfosalicylic acid was determined and the

specific turbidity calculated and compared with that of albumin from the same sera without acetone-ethanol precipitation. The figures in Table III show that, while there is a difference in the specific turbidities of albumin which has and which has not been precipitated by acetone-ethanol, these values bear a constant relationship to one another. This indicates that the cause of the low specific turbidity of albumin in acute infections cannot be separated from the albumin by acetone-ethanol and that it is due to a change in the precipitate itself. Such a change might either be the precipitation of varying amounts of some other substance (for example, carbohydrate or lipid on the albumin-sulfosalicylic acid precipitate) or the presence in the albumin filtrate in varying proportions of two or more protein substances having different specific turbidities. Lipid contamination is unlikely to be the explanation since acetone-ethanol precipitation would probably remove much of this and the relationship apparent in Table III would not exist.

Fig. 1.

EXPERIMENTS WITH AQUEOUS-METHANOL FRACTIONATION OF SERUM PROTEINS

Pillemer and Hutchinson³ have shown that their method of fractionation gives an albumin:globulin ratio which agrees more closely with that obtained by electrophoresis than does Howe's method. Table IV gives the results of simultaneous serum albumin estimations by the two precipitation methods together with the specific turbidities of both albumin fractions.

It will be seen that sodium sulfate invariably precipitates less protein than does the methanol reagent, a result noted by Pillemer and Hutchinson. The difference is small in normal cases (Cases 47 to 50), larger in cases of acute in-

fection, and represents protein precipitated by the methanol reagent but not by sodium sulfate. If this portion is calculated as a percentage (Table IV, column 3) of Howe's albumin, of which it forms a part, it is seen to vary closely with the specific turbidity of the latter (see Fig. 1).

When the last two columns of Table IV are compared, the specific turbidity of albumin separated by the methanol reagent is seen to be high and, unlike that of Howe's albumin, not to fall in infection. The specific turbidity of methanol globulin was determined in a few cases and found to be low (like Howe's globulin), having a value of 4.7.

Three simple fractions are thus distinguishable: (1) a methanol albumin fraction of high specific turbidity; (2) Howe's globulin fraction of low specific turbidity; and (3) a fraction present in Howe's albumin because not precipitated by sodium sulfate, and also present in methanol globulin because precipitated by the methanol reagent. Since the specific turbidity of methanol globulin is low, this third fraction must have a low specific turbidity too. The reduced specific turbidity of Howe's albumin is therefore explained by the presence in it of this material having a low specific turbidity.

COMMENT

Normally the amount of the third fraction is small, but in certain acute infections it may amount to as much as 40 to 50 per cent of Howe's albumin. Since the change is accomplished within a day or two of the onset of the infection and coincides with a sudden drop in methanol albumin, it is reasonable to suppose that it is formed by the modification of part of the albumin. This "modified albumin," like globulin, is precipitated by the methanol reagent and has a low specific turbidity; but like albumin, it is not precipitated by a 22.2 per cent solution of sodium sulfate.

Tillett and Francis⁶ have demonstrated by bacteriologic methods the presence of a nonspecific protein substance, called by them C protein, in the serum of patients with acute infections. This substance was shown by Abernethy and Avery⁷ to be associated with the albumin fraction when globulin is precipitated by ammonium sulfate, while by electrophoresis Perlman, Bullowa, and Goodkind⁸ have found it in the alpha-1 globulin fraction. These observations suggest that C protein might be the same as the modified albumin described in the foregoing. Modified albumin, however, is not precipitated by 50 to 70 per cent saturation with sodium sulfate as is C protein, according to MacLeod and Avery.⁹ Löfström¹⁰ has produced evidence that his nonspecific capsular swelling substance is identical with C protein, but further work is required to confirm the strong presumption that these three substances are one and the same.

SUMMARY

1. In the serum of patients with certain acute infections, a protein is present which differs from normal serum albumin and serum globulin.
2. It appears during the first few days of the infection and is probably formed from serum albumin.

3. This "modified albumin" resembles serum albumin in that it is not precipitated by a 22.2 per cent sodium sulfate solution, but resembles serum globulin in that it is precipitated by a suitable strength of methanol in water.

4. The production of turbidity with sulfosalicylic acid and the estimation of the "specific turbidity" can be used in the investigation of a protein.

LABORATORY METHODS

A SIMPLIFIED METHOD FOR THE PRESERVATION OF BACTERIA BY DESICCATION IN VACUO

M. FROBISHER, JR.,* E. I. PARSONS,† S. E. PAI,‡ AND S. HAKIM§
BALTIMORE, MD.

WITH THE TECHNICAL ASSISTANCE OF ELSIE LANKFORD

THE presence of water in liquid form being a sine qua non of active life, the removal of water or, what is almost equivalent from a physiologic standpoint, its immobilization by freezing puts an end to detectable physiologic activity. Life, however, or at least viability, is not necessarily terminated, and this fact is the basis of several methods for the preservation of bacteria in an inactive condition for long periods. Probably the earliest use of this principle was made by Shattuck and Dudgeon in 1912.¹ Processes for preserving bacteria by desiccation after freezing were described by Rogers² in 1914 and by Swift³ in 1921. Brown^{4,7} devised a simpler method using only desiccation in vacuo at room temperature, and first showed one of us (M. F., Jr.) how to use it. Brown⁷ reported the survival of streptococci, diphtheria bacilli, pneumococci, and other bacteria for periods of from four to twelve years. A modification of his process was described by Leitson⁵ in 1936. There is evidence⁶ to indicate that the principal function of the vacuum in these processes is that of speeding desiccation, which in turn stops autolysis and other intracellular processes which would prove lethal, although withdrawal of oxygen also doubtless reduces the rate of death of the desiccated cells. Any factors, such as higher and more rapidly produced vacuum, thinner layers of fluid, more effective dehydrating agents, etc., which speed up removal of water, add to the efficacy of the method and probably permit prolonged survival of the more delicate organisms.

In a study of *Serratia marcescens*, Naylor and Smith⁹ have shown that high percentages (99 per cent) of cells survive lyophilization if aerated, young cultures are suspended in a solution containing ascorbic acid, thiourea, NH_4Cl , and dextrin at pH 6 to 7. A high vacuum is necessary to high percentage

||The older preparations of bacteria listed in this paper were found by one of us (M. F., Jr.) in 1930 to be viable in jars in which the original vacuum no longer persisted after several years of storage at room temperature and transoceanic shipment, unrefrigerated, lasting several weeks in tropical waters. These same jars of cultures, with the same vials, are included in this latest (1946) series of viability tests.

of survival. Attention is called also to the work of Stark and Herrington¹⁰ who published data on differences in resistance of various species to drying in vacuo. Their remarks on free and bound water are of interest. Rahn¹¹ has given an excellent review of data on the susceptibility and fate of bacteria under desiccation and a discussion of the protective effect of various suspending materials. It seems to be generally agreed that organic colloids have a protective action as a rule, while, in general, contact with oxygen lessens the survival time of the bacteria. In the present study no attempt was made to obtain data on numbers of bacteria surviving after various intervals.

Several processes are in current use in which intracellular water is first immobilized by instantaneous freezing. The effect of this rapid freezing is vitrification rather than crystallization.¹² The water is afterward removed by producing a vacuum in the vessels containing the frozen material. This results in sublimation.^{13, 14} The basic principle of this process was used by Sawyer and co-workers¹⁵ for the preservation of yellow fever virus in their early studies, and it proved highly effective. Instantaneous freezing followed by storage at extremely low temperatures (-76°C.) was shown by Turner and associates^{16, 17} to be a most effective means of preserving living *Treponema pallidum* and other spirochetes, as well as viruses, in status quo for long periods. More recent studies have shown the applicability of freezing as a means of preserving protozoa and metazoa.¹⁸

The methods of Swift, of Brown, and of Leifson are not, so far as we are aware, satisfactory for long-time preservation of spirochetes and viruses, as is the method of Turner and co-workers, but a wide variety of other organisms may be preserved by desiccation in vacuo for many years without apparent loss of virulence or alteration of other important properties such as colonial form; motility; hemolysis, pigment or toxin production; morphology; staining and fermentative characters. Although a few reports of remarkable longevity of bacteria on ordinary culture media are to be found in the literature,^{19, 20} the usual experience is that stock cultures die off in a few months if not transferred to fresh media. This is inconvenient, time consuming, and expensive and induces alterations in the bacteria, as well as contamination.

This communication is made to describe a simplified method for preservation by desiccation in vacuo, modeled after that of Brown, and to show what may be expected of this simplified method. No claim to greater perfection of final vacuum or permanence of closure is made. The principal advantages are simplicity, availability, effectiveness, and low cost under a variety of conditions. The only special apparatuses needed are a good vacuum pump, such as the "Ceneo Hyvac," and a Pyrex vacuum desiccator provided with a one-hole rubber stopper connected to the pump. A one-pint Mason fruit jar, about 100 Gm. of CaCl_2 , and 1 ounce of plasticine are the only materials needed for the desiccation. The bacteria are placed, suspended in sterile rabbit blood, in shell vials 8 by 25 mm.,* previously somewhat less than half filled with

*Arthur H. Thomas Co., Catalogue No. 3648.

"washed and ignited" sea sand, plugged with cotton, and sterilized (Fig. 1, A). A good supply of these vials prepared ahead of time makes the preservation of bacteria in *vacuo* very simple indeed. The necessary steps are as follows:

PREPARATION OF CULTURE

1. The desired organism is cultivated on an agar slant of appropriate composition. After good growth has developed, about 0.5 ml. of sterile, defibrinated or citrated rabbit's blood is placed on the slant and the growth is scraped off the agar and emulsified in the blood. This yields a much heavier suspension than would be obtained by desiccating a broth culture, and the blood, it is believed, when dried on the bacteria, forms a protective coating around them. Heller²¹ has recently shown blood to be the best material for desiccation.

Fig. 1.—A, Sterile vial; B, pipette; C, blooded vial; D, cotton; E, plasticine.

2. A capillary pipette with 1 ml. rubber bulb (Fig. 1, B) is used to take up the blood and transfer it to a sterile shell vial containing sand. The tip of the pipette containing the blood is gently worked downward through the sand until it is at the bottom of the vial and the blood is then made to rise slowly through the sand, thoroughly wetting it by moving the tip of the pipette about gently. Keeping the tip of the pipette at the bottom of the vial, one now withdraws as much of the blood as possible, leaving the sand grains coated with the bacteria-bearing blood. If too much loose blood is left in the vial, it forms a hard, solid mass when dried, which is very difficult to break up when making subcultures from the vial. It is well, therefore, to separate the sand grains somewhat by pushing them partly up the inner side of the vial with the tip of the pipette before finally removing it, so that the grains will not be glued together in a solid mass but can be taken out in small clumps

for subculture. When the sand has thus been "blooded" and the excess blood removed, the cotton plug is replaced.

3. The plug is pushed down in the vial until the upper half of the vial is full of cotton. With seissors, the protruding portion of the plug is clipped off and the tip of the vial is singed so that no cotton fibers protrude (Fig. 1, *C*). Otherwise they may cling to various objects and be pulled out. India ink labelling, covered with nail polish, is convenient. Adhesive tape may also be used as labels. Gummed paper labels are unsatisfactory.

Desiccation.—

1. In the Mason jar, from which the wire clamp has been removed, place about 100 Gm. of technical or C.P. granular calcium chloride. Over this place a ball of cotton sufficient to hold the calcium chloride in place (Fig. 1, *D*). On the cotton place the labelled vials.

Fig. 2.—Type of desiccator and arrangement of moisture traps and manometer.

2. Roll some of the plasticine on the table into a cylinder with the diameter of a lead pencil (about 8 to 10 mm.) and just long enough to form a complete circle around the uppermost ledge of the jar. It is convenient to determine the proper length for the cylinder of plasticine beforehand by making two marks on the table.

3. Put the plasticine in place on the jar (Fig. 1, *E*) and push it into the depression around the top, molding it about 5 to 8 mm. above the top and flaring slightly outward. Place the lid on the plasticine and press it down so that the bottom of the rim of the lid is about 2 mm. below the level of the topmost rim of the jar. Smooth the plasticine all around and make sure that the closure is complete.

4. Insert a needle through the plasticine seal, pointing it slightly upward so that it will pass between the rim of the jar and the lid. This leaves an opening about 0.5 mm. in diameter for the escape of air. Be sure the hole is patent.

5. Place the Mason jar inside the vacuum desiccator, close the desiccator tightly, and draw the highest vacuum possible (Fig. 2). It should be at least within 0.1 mm. of barometric pressure. A folded towel should line the desiccator to prevent breakage should the jar topple over.

6. Stop the vacuum pump and, with a *sudden* jerk, withdraw the stopper of the desiccator so that there is a quick, copious inrush of air. The lid of the Mason jar is thus pressed down, occluding the needle hole and firmly squeezing the plasticine ring. The vacuum in the jar will be within a few millimeters of that originally present. This may be verified if desired by including a small, siphon, mercury barometer in the Mason jar before closure. They are not essential but are a useful guide at first. The construction and use of these barometers were described by Brown⁴ and Leifson.⁸

Fig. 3.—Method of handling knife in opening the evacuated jar.

Recovery of the Culture.—

1. A tube of broth is prepared by adding to it a drop of sterile defibrinated blood and a drop of sterile 10 per cent aqueous dextrose solution. Other media, appropriate to the bacteria involved, may be used.

2. The effect of the vacuum in the jar is felt when an attempt is made to remove the cover. Force the blade of a large, strong knife (using the portion of the blade close to the handle) between the edge of the lid and the shoulder of the jar. Rotate the knife on its long axis, lowering the back of the knife and keeping the blade firmly pressed between cover and jar (Fig. 3). A screw-

driver blade can also be used but may chip or crack the lid. A sudden hiss signalizes the destruction of the vacuum. Having removed the lid, scrape the plastieine together to smooth the surfaces and to use again.

3. In preparing to recover the culture, partially remove the cotton stopper from the vial with a fine-pointed forceps. After this, handle the cotton stopper as though it were in a diminutive culture tube.

4. A fairly rigid wire is used to loosen the sand grains and to transfer a few of them from the vial to the broth. A two-inch length of No. 14 iron wire or an unfolded paper clip fastened to a needle holder will serve this purpose very well. After flaming the wire, allow a few moments for it to cool; then plunge it first into the tube of broth to be used for the subculture. This cools and wets it.

5. Then introduce the wetted wire into the shell vial. By moving it about, a few grains of sand are loosened. These adhere to the wet wire and are transferred to the blood-dextrose broth. It is best to transfer about a dozen grains.

6. The plug is replaced in the vial and it is resealed in the Mason jar as described. The blood-dextrose broth is incubated appropriately. Occasionally a longer-than-usual period of incubation (for example, forty-eight to seventy-two hours) is necessary.

RESULTS

During the period from 1925 to 1928 and at various subsequent times, one of us (M. F., Jr.) preserved, by the method described, several hundred cultures of various species of bacteria. Many of these were taken from the vacuum desiccating jars and tested for viability and cultural properties in 1930 and 1936, but no report was made on the results of those studies. The present report includes the 1936 data and also results of tests of the same identical cultures, and of some others, made in 1946. Thus information is available on the survival of several species of bacteria when desiccated in vacuum for periods ranging from about one to approximately twenty-one years.

The data may be briefly summarized as follows: of 42 strains of beta type hemolytic streptococci, only 6 failed to grow after eighteen years. All but 2 of 20 strains of *Brucella bronchiseptica* grew after nine years and 1 lived seventeen years. Four strains of alpha type streptococci lived five years; 3 tested after eighteen years were not viable. Of 8 strains of pneumococci, 5 strains lived five years, 1 for nine years, 2 were not viable after nine and seventeen years, respectively. Six strains of *Streptococcus faecalis* and *Streptococcus liquefaciens* lived seven to nineteen years.

Of 69 strains of the enteric group, survival of *Eberthella typhosa* and *Salmonella* and *Shigella* species was generally noted after seven years, many strains survived nine years, and 1 strain of *Eberthella typhosa* was alive after eighteen years. *Proteus*, *Aerobacter*, and *Escherichia* and paracolon strains in general lived three to nine years. All of 24 *Staphylococcus* strains were viable after nine years and all of 15 tested survived nineteen years. Hundreds of strains of *Corynebacterium diphtheriae* of all types have survived thirteen years.

Genera generally surviving at least five years are *Serratia*, *Microbacterium*, *Pseudomonas*, *Gaffkya*, *Brucella abortus* (1 strain only four years), *Spirillum rubrum*, and *Lactobacillus*. Species not surviving one year were pathogenic *Neisseria* (six weeks to three months), *Brucella melitensis* and *Brucella suis* (three months), *Hemophilus pertussis* and *Hemophilus influenzae* (six weeks or less). One strain of *Parapertussis bacilli* tested after six weeks was found viable.

It may be said of all surviving organisms that the principal distinguishing characters remained unaltered in any respect. Apparently these organisms had been wholly unaffected by their long dormancy.

It should also be emphasized that, with the few exceptions noted, all of the organisms listed here will remain viable without difficulty for at least a year, thus tiding over intervals between class demonstrations very conveniently. They also remain viable in spite of repeated opening and reclosing of the jars. These facts are perhaps of more practical interest than the survival of some species for twenty-one years or more. When stock cultures are constantly in use, it is more convenient, of course, to maintain them on slants in a vegetative state.

SUMMARY

A method of preservation of bacteria *in vacuo* with simple materials is described. It is evident that, for many species, the method is a desirable substitute for maintenance of vegetative stock cultures and has many important advantages, such as simplicity, economy of time, labor, refrigerator space, and materials, as well as stability and portability of the cultures. A few species, such as pathogenic *Neisseria* and *Hemophilus*, did not survive long under the conditions described, but many others survived for periods ranging from one to twenty-one years.

DESCRIPTION OF APPARATUS AND METHOD FOR OBTAINING NASAL WASHINGS

LEON T. ATLAS, M.D.,* BETHESDA, MD.

AT THE beginning of an investigation of the etiology of minor upper respiratory diseases, it became evident that a new method was required for obtaining nasal washings. After several attempts at collecting washings by the usual method (instilling material into the nostrils, gargling, and expectorating), the unpleasantness experienced by the donor was of sufficient magnitude to warrant investigation of a new method.

It is known that the anatomy of the nose and nasopharynx is such that material instilled into one nostril can be evacuated from the other by suction without interfering with oral respiration. This is the basis for the "nasal douche with suction," "Nichols nasal siphon," and similar therapeutic aids which have enjoyed varying popularity for giving comfort to individuals with obstructed upper respiratory passages. Such procedures usually require the patient to close off the posterior nasal space by elevating the soft palate and uvula against the posterior pharyngeal wall. However, with the subject supine and head extended 20 degrees or more (Fig. 1), fluid cannot readily pass into the larynx and trachea, despite the position of the soft palate and uvula, and in our experience the method is innocuous. An apparatus utilizing such a procedure was devised and in numerous trials has proved quite satisfactory.

The equipment is relatively simple, consisting of a sterile apparatus, a frame, and a source of negative pressure.

The sterile apparatus (Fig. 2, A and C) consists of two L-shaped glass tubes with 4 by 4 inch legs (*F*) and 2¼ by 4 inch legs (*X*), inserted into two openings of a three-hole No. 5 black rubber stopper (*R*), with the third opening containing a 6½ inch long glass tube (*A*) connected at its upper end by a 1½ inch flexible tube (*AB*) to a three-way metal stopcock (*SC*). A 13½ inch long flexible tube (*B*) connects the outlet of the stopcock with a nasal tip (*T-1*) by means of a 3½ inch glass tube (*C*). A similar nasal tip (*T-2*) and glass tube (*D*) is attached to a 9 inch long flexible tube (*E*) connecting with the end of the left lateral L-shaped tube (*F*). Nasal tips (*T-1*) have been made in three sizes from red rubber serum bottle stoppers by grinding down the sides.

All glass tubing is 7 mm. diameter Pyrex, annealed after bending. Flexible tubing may be of rubber or plastic but should be resistant to antoclaving and moderate negative pressure.

*Assistant Surgeon (R).

From the Division of Infectious Diseases, National Institute of Health.

Received for publication, May 10, 1947.

In use, the set (wrapped as a unit and sterilized by autoclaving) is unwrapped and inserted by the rubber stopper (*B*) into a 100 ml. round-bottomed Pyrex centrifuge tube (or equivalent) (*CF*) containing 50 ml. of sterile nasal washing menstruum. A sterile 30 ml. syringe (preferably Luer Lock) (*S*) is attached to the stopcock.

The plywood frame (Fig. 2, *B*) for holding together and protecting the apparatus has a gun-shaped pattern. A $\frac{3}{4}$ inch thick plywood block (*L*) with a $1\frac{1}{8}$ inch diameter hemispheric depression and a rectangular opening (*M*) $1\frac{1}{8}$ by $5\frac{1}{2}$ inches support the centrifuge tube. A $\frac{7}{8}$ by $4\frac{3}{4}$ inch rectangular opening (*N*) holds the barrel of the 30 ml. syringe. Three small-

Fig. 1.

grooved pieces of wood (*H-1*, *H-2*, and *H-3*) support the tubing. They are secured to the frame by one screw apiece, which allows them to be turned to fit the tubing in the best possible manner. Attached to the base of the frame is a $1\frac{1}{4}$ inch diameter by $\frac{1}{4}$ inch thick threaded brass tripod socket (Fig. 2, *C*, *TS*). A sturdy camera tripod with telescoping legs and a good pan head is of value in supporting the apparatus at precisely the optimum position beside the donor's nose. Rubber bands conveniently secure the set to the frame, so that various-sized syringes and types of tubes containing nasal washing menstruum can be easily interchanged.

FIG. 2.

Fig. 2 (Cont'd).

A source of suction has been conveniently supplied by a water pump with adapters for various-sized water faucets. The optimum negative pressure is from 5 to 7 mm. of mercury.

TECHNIQUE OF OPERATION

The equipment is assembled as shown in Fig. 2, *C*. The sterile apparatus is unwrapped and the rubber stopper (*R*) inserted into a tube (*CF*) containing sterile nasal washing menstruum. A sterile 30 ml. syringe (*S*) is attached to the stopcock. Rubber bands are used to mount the assembly on the plywood frame.

Fig. 3.

The suction tube (*Y*) is connected to the source of negative pressure. This is adequately tested by manually clamping tube *E* with the stopcock lever down (Fig. 4, *B*, position *a*). At the proper negative pressure, the 50 ml. menstruum begins to froth violently without, however, climbing into the L-shaped tube (*X*) connecting with suction.

The donor is requested to lie on the back with the head extended 20 degrees or more below the horizontal plane of the shoulders and body (Figs. 1 and 3). With the donor's head rotated to the side of the apparatus, nasal washing fluid can run out the side of the mouth into a sterile beaker should

the suction fail and the patient be unable to close off the posterior nasal recess by the soft palate and uvula. The nasal tips (Fig. 2, *C*, *T-1* and *T-2*) are gently but snugly inserted into the external nares and the donor instructed to breathe through the mouth. Usually the nasal tips must be kept in place by the operator, the donor, or an assistant.

Nasal washing is obtained in the following manner (Fig. 4):

1. With the stopcock lever up (Fig. 4, *A*, position *c*), the donor can usually feel the negative pressure. He is instructed not to swallow the menstuum.

2. With stopcock lever down (Fig. 4, *B*, position *a*), 30 ml. of nasal washing menstuum is drawn into the syringe.

3. Stopcock lever is turned to horizontal (Fig. 4, *C* and *D*, position *b*) and the material in the syringe is slowly emptied into the upper nostril, the posterior nasal recess of the nasopharynx, and through the lower nostril back into the apparatus (Fig. 1 and Fig. 4, *C* and *D*). When the syringe is free and the suction working well, the syringe will empty itself at the proper rate. Usually, however, the syringe must be manually operated. If the nasal washing menstuum is pushed through too rapidly (particularly if the suction is not adequate), fluid may overflow at the nasal tips, perhaps flow into the oral pharynx (where the patient may swallow it or expectorate it into a sterile beaker), or flow into the nasolacrimal duct to the eye.

Steps 2 and 3 are repeated as many times as desired. Utilizing this procedure, it is not difficult to circulate rather quickly 30 ml. amounts of menstuum through the nasal passages eight to ten times.

4. When the nasal passages have been sufficiently washed, the stopcock lever is turned up (Fig. 4, *E*, position *c*) so that the negative pressure cleans out both nostrils. The donor is instructed to inhale, sit up, and expectorate the material from the throat into the sterile beaker immediately after the nasal tips are removed. Usually, the expectorated material is only mucus showing no trace of the nasal washing menstuum. Often, however, the sinuses have been irrigated by the the washing procedure and a few milliliters more washing can be collected by having the donor flex the head and blow one side of the nose and then the other into the sterile beaker at intervals for two to five minutes.

The apparatus may be tipped slightly, if necessary, to capture the last few drops of mucus in the tubing. Suction is discontinued. The apparatus is disconnected from the tube containing the washing by pulling out the rubber stopper (Fig. 2, *C*, *R*). The material collected in the beaker may be poured into the tube if desired. The container (Fig. 2, *C*, *CF*) is closed by inserting a sterile No. 6 rubber stopper. Spraying with a vasoconstrictor will maintain the patient's comfort for a number of hours. This has not been necessary when sterile skim milk was used as the nasal washing menstuum.

Sterile skim milk has been the menstuum used for the routine nasal washings because many rickettsial agents survive longer and withstand freezing and drying better when protected by milk.^{1, 2} Since a quantity of mucus has

Fig. 4.

been present in most washings, homogenization in a Waring blender or by hand has been routine. After centrifuging (to remove cellular debris), quick freezing, and storing at -50° C., washings are used for the inoculation of embryonated eggs, human volunteers, and various laboratory animals.

DISCUSSION AND SUMMARY

An apparatus and method for obtaining nasal washings is described. The apparatus and the method of its use have proved quite satisfactory during numerous trials. No complications have resulted from obtaining nasal washings in this manner.

Advantages of such a procedure are as follows:

1. It obtains washings from the nasal passages without serious contamination from oral material.
2. Washings reach areas in the nasal passages (such as sinuses and nasolacrimal ducts) not usually reached by previous methods.
3. Friable epithelial cells and cellular debris in nasal passages are collected more effectively by recirculating the washing material eight to ten times. The etiologic agents sought may be present in this cellular portion.
4. Washings are easily and efficiently collected.
5. Procedure is not as unpleasant as previous methods, and donors report a feeling of well-being and "clearheadedness" following the washing.

A NEW RAPID TECHNIQUE FOR Rh TYPING

CAPTAIN PAUL G. HATTERSLEY,
MEDICAL CORPS, ARMY OF THE UNITED STATES

IT IS being recognized increasingly that human isoimmunization to the Rh factors is a common occurrence. Whereas about only one in twenty-five Rh-negative women who bear Rh-positive infants ever develop Rh antibodies, Diamond¹ and Wiener and Sonn-Gordon² were able to sensitize a very large percentage of Rh-negative volunteers by injections of Rh-positive blood. Diamond,¹ Ross,³ and Hattersley⁴ likewise found Rh antibodies in the serum of about 50 per cent of previously transfused Rh-negative patients, demonstrating that sensitization by transfusion is not, as it has been considered for so long, a relatively rare occurrence. The danger to future pregnancies of such accidental sensitization in women is well established, and the fact is becoming recognized that transfusion reactions due to Rh sensitization occur not infrequently. Consequently, increasing numbers of hospital laboratories are establishing Rh typing as a routine pretransfusion procedure.

There are three important difficulties which are encountered when such a program is introduced: (1) Adequate supplies of reliable and potent Rh typing serum are not always available; (2) Rh typing techniques require skill which many laboratory technicians lack; (3) Rh typing requires time which, when blood is urgently needed, is at a premium.

The first of these difficulties is now largely solved by the increasing use of the hyperimmune or "blocking" antibody, which was first shown by Diamond and Abelson⁵ to be capable, under certain conditions, of agglutinating Rh-positive cells. Sera containing such antibodies are of common occurrence, particularly among individuals sensitized by transfusions, and may reach extremely high titers. They have the further advantage of being more stable than saline agglutinins and, with the techniques suggested by Wiener⁶ and Diamond and Denton,⁷ are equally easy to use.

On the other hand no method of Rh typing which is at once uniformly easy to read and very rapid has yet been reported. The tube techniques, while perhaps the simplest to interpret, have the drawback of requiring incubation. The slide technique of Diamond and Abelson,⁵ while it gives Rh typing in five minutes or less, occasionally gives confusing or equivocal results, and the somewhat less rapid capillary method of Chown⁸ requires a skill of handling which makes it impractical for many smaller laboratories.

While attempting to solve these problems as they existed in this laboratory, it was discovered that when Rh-positive cells are mixed with a high titer hyper-

Received for publication, Feb. 27, 1947.

immune Rh antiserum and immediately centrifuged at high speed, there is gross agglutination which is not readily broken up. On the basis of this observation, the following technique was established:

A potent hyperimmune serum (with alpha and beta antibodies neutralized) is diluted with several volumes of 20 to 30 per cent bovine albumin. One drop of this mixture is placed in a small agglutination tube. An applicator stick is thrust into the elotted or oxalated whole blood to be tested and enough cells carried over to the agglutination tube to make a moderately heavy suspension in the drop of serum.* (If preferred, a small drop of a suspension of cells in their own serum or in saline may be used, taking care that the concentration of albumin in the final mixture does not fall below 15 per cent.) The tube

Fig. 1.—The Rh test, ready to read. Tube on the left shows gross agglutination of Rh-positive cells. Tube on right shows smooth suspension of Rh-negative cells. (Courtesy Letterman General Hospital Photographic Laboratory.)

is shaken to insure mixing and without preliminary incubation is centrifuged at high speed for two minutes. It is then shaken gently and the sediment examined for agglutination. Rh-positive cells show gross clumping which is not readily broken up. Rh-negative cells remain perfectly smooth, without rouleaux (Fig. 1).

Since this technique was introduced into our laboratory, where it has been used in parallel with one of the standard methods, it has proved entirely reliable in more than 1,000 tests. It has been found so easy to handle that even our least skilled technicians have had no trouble with it, and its great speed has on several occasions proved invaluable to us.

Certain precautions are necessary in choosing a suitable serum for use with this technique. Sera with an initial titer in albumin of less than 1,000 are

*This portion of the technique was suggested by Miss Evelyn Tennis of the Community Blood Bank, San Mateo, Calif.

seldom satisfactory, and the final titer should not be below 100. Even among sera of adequate titer some will be found which are insufficiently avid to give satisfactory results, and these sera must be eliminated by trial and error. Care should likewise be taken to standardize the serum as to specificity, for, as shown by Diamond¹ and Hattersley,⁴ hyperimmune antibodies of Rh' (C of Fisher) and Rh'' (E) specificity not infrequently occur, mixed with the more common Rh₀ (D) antibody.

It is felt that if these few precautions are observed this rapid technique should prove of considerable value, particularly in laboratories such as ours where speed and ease of Rh typing are at a premium, and should render it increasingly practical to determine routinely the Rh type of all transfusion cases.

SUMMARY

A new technique of Rh typing is described. It utilizes the readily available Rh "blocking" serum and has the advantage of speed and of ease of reading. It has proved entirely reliable in a series of over 1,000 bloods.

tivity of measurement as determined with the Coleman Junior Spectrophotometer is greatest at 540 millimicrons. A filter with the maximum transmittance at 540 $m\mu$ was used in the routine determinations with the Evelyn colorimeter.

Recovery Experiments.—Serum was obtained from various species by allowing freshly drawn blood to clot and storing it in the refrigerator for a few hours. Each sample of serum was analyzed for magnesium according to the technique described. Known amounts (10 to 20 μg per milliliter) of magnesium, as magnesium sulfate, were then added to the serum and analyses were run to measure the recovery of the added magnesium. Data were obtained from twenty-four determinations on twelve different serum samples. The mean recovery of the added magnesium was 99.84 per cent, with a standard deviation of ± 1.44 per cent. Whole blood was oxalated by means of potassium or sodium oxalate. The procedure used in the recovery experiments was the same as that used with serum, except that 20 to 40 μg of magnesium were added. The mean recovery of thirty-seven determinations on twelve different blood samples from different species was 99.47 per cent, with a standard deviation of ± 1.32 per cent.

Urine obtained from male adults was used in the recovery experiments. The mean recovery for ten determinations of added magnesium to ten samples was 99.65 per cent, with a standard deviation of ± 2.22 per cent.

TABLE I. RECOVERY OF MAGNESIUM ADDED TO SAMPLES OF SERUM, WHOLE BLOOD, AND URINE

	SERUM	WHOLE BLOOD	URINE
Number of samples	12	12	10
Number of determinations	24	37	10
Mean per cent magnesium recovered	99.84	99.47	99.65
Standard deviation	± 1.44	± 1.32	± 2.22

In all recovery experiments there was no constant error in the method since the per cent recovery was neither consistently above nor below the expected value.

Ten samples of serum were independently analyzed by the described method on different days by two different analysts using two entirely different sets of reagents. The correlation coefficient between the magnesium values obtained by the two different individuals was $\div 0.985$. Also in analyses of ten samples of whole blood, different amounts of filtrate (3 to 5 ml.) were used and a correlation coefficient of $\div 0.961$ was obtained. There was no constant error, for the values obtained using smaller aliquots were neither consistently above nor below the values obtained using larger aliquots.

Remarks.—Calcium and phosphate ions interfere, but fortunately these substances have not been found to be present as blood components in concentrations that appreciably influence the results. The calcium concentration, as reported by Gillam,⁴ in order to interfere must be at least 500 μg per milliliter in the solution that is read photometrically. The phosphorous concentration must be kept below 100 μg per milliliter since it interferes by buffering the solution and lowering the hydroxyl ion concentration. If in urine, for

example the urine of a calf receiving only a milk diet for some time, the phosphorus-magnesium ratio is wider than 200:1, the method described in this paper is limited to a semiquantitative determination. If such urine is to be analyzed, the technique for soil extracts described by Gillam⁴ is recommended.

The hydroxyl ion concentration must be carefully controlled. The higher the hydroxyl ion concentration, the greater the density of the solution. Acid, base, or buffering solutions (hydroxylamine hydrochloride solution) must be added carefully so as to insure the same amounts in the unknown sample as in the blank. In the method described by Garner⁷ the alkalinity of the unknown was greater than that of the blank, for the method did not take into account the trichloroacetic acid removed from the solution by the precipitation of the proteins. The values were higher than those obtained when the trichloroacetic acid had been removed.

The temperature of the solution affects the optical density of the solution and must be controlled. The specific temperature is not of importance but the unknown sample should be read at approximately the same temperature as the standards. It is more convenient to adjust to room temperature; therefore the temperature selected was 25° C.

TABLE II. THE MAGNESIUM CONTENT OF WHOLE BLOOD AND PLASMA

SPECIES	WHOLE BLOOD			PLASMA OR SERUM		
	NUMBER OF ANIMALS	AVERAGE (MG./100 ML.)	RANGE* (MG./100 ML.)	NUMBER OF ANIMALS	AVERAGE (MG./100 ML.)	RANGE* (MG./100 ML.)
Human being	6	3.82	3.58-4.50	6	2.14	2.02-2.22
Sheep	6	2.79	2.61-2.92	6	2.27	2.02-2.47
Rabbit	7	5.23	4.72-5.73	6	2.45	2.05-2.97
Pig	6	5.26	5.03-5.60	8†	2.46	2.20-2.84
Cattle	6	2.04	1.95-2.09	45†	2.13	1.23-2.75

*Range refers to observed concentrations.

†Serum.

Magnesium Content of Blood.—The magnesium content of whole blood and plasma or serum from five different species has been determined by the method reported here. The bloods were collected at random from healthy individuals and animals. The results (Table II) show that the concentration of magnesium in the plasma or serum varies little among the different species. There was considerable variation in the magnesium content of whole blood. The magnesium content of the whole blood of the rabbit and pig was around 5.24 mg. per 100 ml., whereas for cattle and sheep the values were less than 3.0 mg. per 100 milliliters. In the human being, sheep, rabbit, and pig the concentration of magnesium in the whole blood is greater than that in the plasma or cells. These observations are in accord with reports on the distribution of magnesium in the blood of cattle⁸ and human beings.⁹

SUMMARY

A method has been described for the photoelectric or spectrophotometric determination of the magnesium content of serum, plasma, whole blood, erythro-

cytes, and urine. The blood proteins are precipitated by means of tungstic acid, and the magnesium is measured by the amount of the red magnesium hydroxide-titan yellow complex produced. The mean recoveries of added magnesium ranged from 99.5 to 99.8 per cent with whole blood, serum, and urine.

Data are presented on the magnesium content of whole blood and plasma for the human being, rabbit, pig, sheep, and cattle.

RAPID TITRIMETRIC MICROMETHOD FOR THE DETERMINATION OF NONPROTEIN NITROGEN

F. RAPAPORT, PH.D., AND F. EICHORN, M.D.
PETAH TIQA, PALESTINE

IT IS possible to determine the nonprotein nitrogen in whole blood, serum, or plasma within a few minutes with the accuracy of the Kjeldahl method¹ but without the troublesome digestion and distillation. An alkaline hypobromite-boric solution is added to a protein-free filtrate and the excess of bromine is titrated iodometrically.^{2, 3} Boric acid has been added to the deaminating solution to prevent any interaction between the bromine and the glucose present in protein-free filtrates, since even large amounts of glucose are bound by boric acid. Not only urea and ammonia, but all physiologic amino compounds are included, the latter being deaminated simultaneously. Even amino acid mixtures obtained by protein digestion with trypsin in the preparation of broth give identical results using this and the Kjeldahl method. Indole compounds which contain nitrogen in their ring system do not affect the result since normal blood contains only traces of these compounds.⁴ Even in uremia, indole compounds do not interfere since their nitrogen contribution does not rise above 0.4 to 0.5 mg. per cent.

METHOD

Reagents.—

A. Deproteinizing Solutions:

1. Dissolve 20 Gm. sodium sulfate anhydrous in water, add 69 ml. of $\frac{2}{3}$ N sulfuric acid and fill the flask with water to the 1,000 ml. mark.

2. Dissolve 5 Gm. sodium sulfate and 8.3 Gm. phosphomolybdic acid in about 200 ml. water; add 20 ml. of 5 N sodium hydroxide solution and boil gently over a burner for thirty minutes. Cool; add 10.6 ml. of concentrated sulfuric acid, then 10 Gm. cadmium sulfate, and make up to final volume of 1,000 milliliters.

Cadmium sulfate has been added to the deproteinizing solution in order to precipitate compounds which would evolve hydrogen sulfide and which would therefore use up relatively large amounts of bromine. However, cadmium sulfate precipitates all sulfur compounds.

B. Preparation of Deaminating Reagent:

1. Boric acid solution. Dissolve 84.5 Gm. boric acid and 15.6 Gm. sodium hydroxide in about 500 ml. water and boil for thirty minutes. Cool and make up to one liter.

2. Sodium fluoride solution saturated.

From the Bellinson Hospital.
Received for publication, April 15, 1947.

3. Sodium hydroxide, 27 per cent. Made by dissolving 27 Gm. in 100 ml. of water.

4. Bromine solution. Dissolve 20 Gm. potassium bromide in about 50 ml. water; add 8 Gm. (2.5 ml.) pure bromine; mix until bromine dissolves and make up to one liter.

If it is more convenient, the bromine solution may be made as follows: Dissolve 32 Gm. potassium bromide and 2.8 Gm. potassium bromate (KBrO_3) in some water in a liter volumetric flask; add 100 ml. of normal sulfuric acid and after waiting for thirty minutes, fill up to the 1,000 ml. mark with water.

5. Boric acid-fluoride mixture. Mix 5 parts boric acid solution (1) with 3 parts sodium fluoride (2) and 1 part 27 per cent sodium hydroxide (3) [for example, to 250 ml. (1) add 150 ml. (2) and 50 ml. (3)]. This mixture keeps well.

6. Deaminating reagent. Just before use add 1 part of bromine solution to 9 parts of boric acid-fluoride mixture.

C. Titration Reagents:

1. Sodium thiosulfate N/200.
2. Potassium iodide crystals.
3. Starch solution 0.25 per cent.
4. Hydrochloric acid 18 per cent (Approximately 5 N).

Procedure.—Pipette 2.9 ml. deproteinizing solution (A1) into short, stoppered test tubes. With a capillary pipette add 0.1 ml. blood directly from finger and lake by repeatedly drawing fluid in and out of the pipette. Add 1 ml. of deproteinizing solution (A2). Mix, let stand five minutes, and then centrifuge or filter (0.2 ml. blood may be used with 5.8 ml. deproteinizing solution, and 2 ml. of phosphomolybdic acid).

Into two wide test tubes or flasks, pipette 3 ml. of clear filtrate and 5 ml. of deaminating solution. Mix and, after two minutes, add a few crystals of potassium iodide and 2 to 3 ml. of hydrochloric acid to each sample and titrate with N/200 sodium thiosulfate until yellow; finally, add a few drops of starch solution and titrate until disappearance of the blue color.

As a blank, mix 3 ml. of deproteinizing solution (1) with 1 ml. of deproteinizing solution (2); take 3 ml. of the mixture to add to 5 ml. of deaminating solution and titrate with the thiosulfate solution.

Calculation.—Since $2\text{NH}_3 + 6\text{Br} = 6\text{HBr} + \text{N}_2$, one atom of N is equivalent to 3 atoms Br. Thus 1 ml. N/200 thiosulfate is equivalent to

$$\frac{14 \text{ (atomic weight N)}}{3 \times 200} = 0.0233 \text{ mg. } \frac{160}{0.075 \text{ (ml. sample used)}} \times 0.0233 = 31.1.$$

From the milliliters of thiosulfate used for the blood sample, subtract the milliliters used for the reagent blank, and obtain the milliliters actually used by the blood sample. Multiply this by the factor 31.1 to obtain the nitrogen in milligrams per cent.

ALTERNATE METHOD

Reagents.—*A. Deproteinizing Solution* (Modified Abrahamson's Reagent)²:

Dissolve 4.48 Gm. sodium tungstate, 2 Gm. sodium citrate and 6.4 Gm. sodium sulfate in about 500 ml. water; add 44.8 ml. of a normal sulfuric acid or 67.2 ml. 2/3 N sulfuric acid; then add 2 Gm. cadmium sulfate and fill volumetric flask to 1,000 milliliters.

Procedure.—Pipette 5.0 ml. deproteinizing solution A into a short test tube. Wash in 0.1 ml. finger-tip blood from capillary pipette. After five minutes, centrifuge or filter. Place 4 ml. of clear filtrate in another tube and continue with deamination and with the thiosulfate titration as described. As a blank, use 4 ml. of deproteinizing solution and 5 ml. of deaminating solution.

Calculation.—Subtract the number of milliliters of N/200 sodium thiosulfate used in the blank determination from the amount used by the blood sample, and multiply by 29.75 as a factor to obtain the amount of nitrogen in milligrams per cent, since 0.0784 ml. of blood is the amount of blood used in the determination.

SUMMARY

A rapid, accurate, and convenient titrimetric procedure has been described for the estimation of nonprotein nitrogen in serum, plasma, or whole blood. Since this method does not require digestion and distillation of the sample, many errors are avoided which are inherent in the longer procedure.

TABLE I. COMPARISON OF THE PRESENT METHOD WITH THE KJELDAHL METHOD FOR DETERMINATION OF NONPROTEIN NITROGEN

FIBRIN APPEARANCE TIME

A ROTATING TUBE METHOD FOR ESTIMATING THE CLOTTING TIME OF THE BLOOD

MURRAY J. WIENER, M.D., AND SHEPARD SHAPIRO, M.D.
NEW YORK, N. Y.

THERE is great need for a test to reflect more reliably the fine alterations in the over-all picture of the coagulability of the blood than is possible by current methods. The results are influenced especially by (1) the constituents of the blood, (2) crude technical manipulation, and (3) uncertain criteria for fixing the time of clotting, the end point. Items 2 and 3 are amenable to control, and a technique which would make them more constant or precise would yield a more critical test than those in general use.

Considerable variation in the content, or activity, of one or more factors in the clotting process may occur without demonstrable alteration in the coagulation time, as it is commonly determined. This is well demonstrated in dicumarol- or salicylate-induced hypoprothrombinemia. It is possible, however, that a more sensitive test would reflect regularly the inhibition of the clotting process in the presence of reduced activity of a single component such as prothrombin.

In the manipulation of the blood specimen there are two major factors which alter the coagulation time: (1) the nature of the container and (2) trauma to the formed elements of the blood.

Nature of the Container.—When kept in "nonwetable" vessels, blood may clot more slowly. This can be controlled by using the same type of vessels of approximately equal size and smoothness at all times. Inconstancy in the relationship of glass contact surface to total volume of blood will give considerable alteration in clotting time. Thus, by the Howell technique, using 21 mm. diameter tubes, the clotting time of normal blood may extend to sixty minutes; by the Lee-White method, using tubes of 8 mm. in diameter, the normal range for blood coagulation is from four to sixteen minutes; by the capillary tube methods, with tubing of less than 1 mm. in diameter, the normal clotting time is likewise highly variable. Nor can blood be poured indiscriminately against the glass surfaces of tubes without affecting adversely the reliability of the test. This can be demonstrated by comparing the Lee-White clotting time of a slightly tilted and of a fully tilted set of tubes. We have observed that not only the frequency and angle of tilting, but also the constancy of direction of tilting make a difference in the clotting time.

Trauma to Blood Constituents.—Blood which is forced under pressure through a small aperture, or is shaken or stirred, will clot promptly due to trauma to the formed elements, especially platelets, and to the liberation of the coagulating factors into the blood sample. To obviate this, it is essential that the blood be transferred consistently and gently.

From the Third (New York University) Division, Goldwater Memorial Hospital, Welfare Island, and the Department of Medicine, New York University College of Medicine.
Received for publication, March 5, 1947.

Lee-White Coagulation Test.—If a tube containing blood is tilted at regular intervals, the viscosity of the blood increases gradually until it forms a gelatinous mass which projects above the liquid portion when the position of the tube is changed. Later, the blood solidifies except for a small amount of liquid at the rim. Eventually, when the whole mass becomes solid enough to permit inversion of the tube without spilling, the end point is reached. Frequently the end point remains in doubt for several minutes, adding to the crudeness of the procedure. This difficulty is magnified in cases of disturbed clotting found in heparin medication and in blood dyscrasias.

FIBRIN APPEARANCE TIME

The following procedure minimizes the variables noted previously by providing (1) a nontraumatic manipulation, (2) constant agitation, and (3) a precise end point.

Fig. 1.—Photograph of apparatus showing tube attached to motor (see text).

In its liquid state, a small quantity of unmodified blood will remain, by virtue of its cohesive force, in a concave smooth container in the form of a large drop and will not attach itself to the surrounding surface. The instant blood commences to clot, fibrin forms and, because of its adhesiveness, clings to the container wall. This change is immediately detectable if the blood is contained in a transparent tube rotating at a slow and constant rate. Then, when fibrin forms it attaches to and climbs with the rising wall.

Apparatus (Fig. 1).—

1. A transparent tube of glass or plastic material about 11 mm. in diameter with a bulbous dilatation at one end from which there extends an eccentrically directed opening for the introduction of the blood sample.
2. A motor which rotates at a constant slow rate of about 1 revolution per minute.

3. An attachment to the shaft of the motor to hold the tube (Fig. 1).

Procedure.—A sample of blood is obtained by smooth venipuncture. At the instant of venipuncture the stop watch is started. One-half of one milliliter, about 8 drops, is immediately introduced into the bulbous end of the tube, which is attached to the shaft of the motor, and the motor is started. The blood forms into a large drop which remains in the well of the bulb. As soon as fibrin forms, the strands adhere in a growing mass to the surrounding bulb and climb with the rising wall. This appearance of a continuous mass of fibrin is the end point.

In one hundred estimations, made in eighty normal individuals, in which the rotating tube was subjected to the heat of a strong electric light, the time of fibrin appearance varied between 3.5 and 5 minutes. In thirty-one tests made in an equal number of cases at room temperature there was an average deviation of 33 seconds from a mean of 5 minutes and 18 seconds. We accept 4 to 6 minutes as the normal range at room temperature. In all normal cases in which blood was drawn gently after smooth venipuncture, the clotting time fell within the above range.*

A comparison was made of the clotting time of blood by the Lee-White method and the rotating tube method. Specimens of blood were obtained by "clean" venipuncture on twelve patients with a variety of chronic diseases. Each sample was divided instantly, appropriate quantities being used for the respective tests. The average results obtained are shown in Table I.

TABLE I

	AVERAGE TIME (MIN.:SEC.)	AVERAGE DEVIATION	% DEVIATION FROM AVERAGE
		FROM MEAN (MIN.:SEC.)	
Rotating tube	5:15	0:39	12
Lee-White	10:38	2:36	24

From these data it can be seen that while the average clotting time by the Lee-White method is only twice as long as that by the rotating tube, the average deviation is four times as great.

The figures obtained are shown in Table II.

TABLE II

	ROTATING	LEE-WHITE
1	5:00	14
2	6:20	14
3	5:50	13
4	5:20	12½
5	6:15	8½
6	4:45	11
7	4:05	5½
8	4:10	8
9	5:25	7
10	5:00	8½
11	6:10	13
12	4:45	12.5

*If it is desired to make the test at body temperature, this can be accomplished by placing a strong electric bulb near the apparatus. The distance must be determined by trial and the apparatus kept at the optimum point for a time interval adequate to insure the desired temperature.

Patients being treated with dicumarol present good correlation between prolonged prothrombin time and fibrin appearance in the rotating tube (Fig. 2). Fibrin appearance time will not replace prothrombin time estimations in following dicumarol therapy, but it may extend the interval between essential prothrombin time estimations to about every five days. Fibrin appearance time is taken daily at the bedside. It has been found to become prolonged to about ten minutes at the dicumarol therapeutic level. It restores to normal more promptly than the prothrombin time. As soon as the fibrin appearance time becomes normal the prothrombin estimation is made again, and further dosage of dicumarol is determined from these prothrombin time values.

Fig. 2.—Chart illustrating extended fibrin appearance time in relation to prolonged prothrombin time of whole and diluted (12.5 per cent) plasma after 1,100 mg. of dicumarol.

The fibrin appearance method has a high correlation in heparin therapy as well. While the end point in the Lee-White method is vague and uncertain after heparin, the fibrin, appearance time method reveals a clear and unmistakable end point. We have found a good therapeutic level after heparin to be about twelve minutes.

In blood dyscrasias, characterized by extended coagulation time, the end points are likewise clear and the results reproducible. Thus we have found the fibrin appearance time to be 35 minutes in hemophilia. In thrombocytopenic purpura the time has been definitely, although only slightly, prolonged during the active bleeding phase of the disease. In the presence of clinical thrombosis in the acute stage the fibrin appearance time has been found to be normal or reduced.

SUMMARY

A method of precisely determining the over-all coagulability of unmodified blood by estimation of the time required for the appearance of fibrin is described. The test is made in a transparent tube rotating at a constant and slow rate.

It registers small increases in coagulation time, thus permitting a more critical estimation of alteration in blood coagulability.

It is applicable to the determination of the maintenance of therapeutic levels of heparin and/or dicumarol. Although it does not eliminate entirely the need for prothrombin time estimations after dicumarol, it may prolong considerably the intervals between essential prothrombin time estimations.

It may be possible to demonstrate acceleration of coagulation time by the new procedure.

A RAPID TEST FOR ALBUMIN AND SUGAR IN THE SAME MEASURED SAMPLE OF URINE

N. R. BLATHERWICK, PH.D., AND JOSEPH H. DWORKIN, B.S.
NEW YORK N. Y.

TESTS to determine the presence of albumin and sugar in urine are ordinarily made on two different samples of the specimen. It would be advantageous to be able to make these two tests on the same measured sample of urine. The procedure described permits this to be done. Sulfosalicylic acid is the reagent used for albumin, and Benedict's solution, for sugar.

METHOD

Deliver 8 drops of urine into a test tube having an outside diameter of 19 millimeters. Next add 0.8 ml. of a 4.5 per cent solution of sulfosalicylic acid. The almost immediate appearance of a white, turbid precipitate or cloud indicates the presence of albumin. Now add 5 ml. of Benedict's solution and shake the tube well to mix the contents. Proceed as usual by boiling over the free flame for one or two minutes or by heating in a boiling water bath for five minutes. Allow the tube to cool in the air spontaneously. Interpret the result in the customary manner. This may be called the laboratory method.

The following modification should be useful to physicians, insurance medical examiners, visiting nurses, and others who do not wish to bother with reagent solutions. The test may be performed in the home, if desired. Deliver 5 drops of urine into a test tube having an outside diameter of 15 mm. and then add 10 drops of water. Drop in one sulfosalicylic acid reagent granule* and shake the contents gently for a second or two. After two minutes look for the turbidity described in the preceding paragraph. The granule does not dissolve, but it carries sufficient sulfosalicylic acid which is released to precipitate the protein. Proceed with the test for sugar by dropping in one effervescent sugar reagent tablet,† the active ingredients of which are cupric sulfate, sodium hydroxide, sodium bicarbonate, and citric acid. About fifteen seconds after the reaction has ceased, a typical copper reduction test will be obtained in the presence of sugar.

DISCUSSION

Sulfosalicylic acid is recognized as an excellent reagent for the precipitation of albumin in urine. The quantitative method described by Kingsbury, Clark, Williams, and Post‡ is widely used by life insurance companies, hospitals, and

From the Biochemical Laboratory of the Metropolitan Life Insurance Company.

Received for publication, May 10, 1947.

*Sulfosalicylic acid reagent granules No. 2 are manufactured and sold by Cargille Scientific Inc., New York, N. Y.

†Sugar reagent tablets are manufactured by Ames Company, Inc., Elkhart, Ind.

‡Kingsbury, F. B., Clark, C. P., Williams, G., and Post, A. L.: The Rapid Determination of Albumin in Urine, *J. LAB. & CLIN. MED.* 11: 981, 1925.

clinics. It was necessary in devising the method described herein to show only that the presence of sulfosalicylic acid used in the test for albumin does not interfere with the test for sugar by Benedict's solution. The sugar reagent is sufficiently alkaline to neutralize the acid and it functions as though the sulfosalicylic acid were not present. Two series of urine containing 0.25, 0.5, 0.75, 1.0, and 1.5 per cent glucose were run, using in one case 0.8 ml. of water and in the other 0.8 ml. of a 4.5 per cent solution of sulfosalicylic acid plus 5 ml. of Benedict's solution. The two series were heated simultaneously in a boiling water bath for five minutes. Upon cooling, no difference in the results could be observed.

SUMMARY

A rapid method for detecting albumin and sugar in the same measured sample of urine is described. .

MORPHOLOGIC CHANGES IN THE LYMPHOCYTES OF PERSONS EXPOSED TO IONIZING RADIATION

ANNAMAE DICKIE AND LOUIS H. HEMPELMANN, M.D.
LOS ALAMOS, N. M.

EXAMINATION of supravital preparations of the blood of persons exposed to ionizing radiations and toxic chemicals at the Los Alamos Scientific Laboratory has revealed the presence of an unusually large number of refractive neutral red bodies in the cytoplasm of the circulating lymphocytes. These bodies are also present in smaller numbers in lymphocytes of unexposed persons. They can be distinguished from intracellular vacuoles which also stain with neutral red. The increase in neutral red bodies is evident even when exposure to radiation is within the tolerance range, eq., not greater than 0.1 roentgen of x-rays or gamma rays per day delivered to the entire body. The neutral red bodies are found in increased numbers after acute exposure to doses of ionizing radiation which do not affect the total white blood cell count, the total lymphocyte count, or the differential blood cell picture.

METHODS AND MATERIALS

This study covers a two-year period from 1944 to 1946. All of the subjects have been employed at the Los Alamos Scientific Laboratory. Except for those in control group, all persons have been engaged in work which has resulted in exposure to ionizing radiation or toxic chemicals. With rare exceptions, the exposure was limited to one type of ionizing radiation or to one kind of chemical. The subjects included in this report were carefully selected for uniformity of sex and age. The conditions under which the study was carried out were kept as uniform as possible. The subjects were healthy, adult men, the great majority of whom were between 20 and 30 years of age. All were in residence at the Los Alamos project. All subjects were essentially of the same economic status. Each blood sample was taken in the morning between eight-thirty and ten o'clock. Excluded from this series was any subject showing evidence of illness (except for a group of ambulatory controls specifically chosen for upper respiratory infections), extreme fatigue, or hematologic abnormalities of known or unknown etiology (except radiation).

As far as can be ascertained, dissimilarities between the control and the exposed subjects were limited to occupation and number of blood counts per subject. All exposed persons were engaged in laboratory work of some sort,

This paper is based on work performed under Contract No. W-7405-Eng-36 with the Manhattan Project at the Los Alamos Scientific Laboratory of the University of California.

From the Los Alamos Scientific Laboratory.

Received for publication, June 1, 1947.

while the occupations of the control group ranged from physical work performed out-of-doors to clerical work. Relatively few persons in the control series worked under conditions comparable to those under which the exposed subjects worked. As far as the number of blood counts per subject is concerned, not more than one or, at the most, two blood counts were obtained for each control, while monthly or bimonthly blood counts were done on the exposed personnel. In many cases this was the only blood count which a control subject had experienced. The emotional response in some of these individuals cannot be ruled out as a factor which may have modified their blood pictures.

Every practical means was used to minimize technical errors and to reduce the statistical variation of individual counts. All pipettes and hemocytometer chambers used in this study were standardized by the United States Bureau of Standards. The red blood cell count was determined by examining two sides of a hemocytometer chamber filled with well-mixed diluted blood from a single pipette. Both sides of two chambers containing mixed diluted blood from two pipettes were counted to determine the white blood cell count. The hemoglobin content of the blood was estimated by means of the oxyhemoglobin method of Evelyn.¹ The differential leucocyte picture was obtained by examining 300 cells—200 on a dried film of blood stained with Wright's stain, and 100 in supravital preparations. In most cases, the number of refractive neutral red bodies in fifty lymphocytes was counted and recorded.

Since the morphologic change in the lymphocytes reported in this article can be visualized only in supravital preparations, a detailed account of this technique as used in the Los Alamos Medical Laboratory will be given:

Microscopic slides and cover slips are carefully cleaned with potassium dichromate-sulfuric acid solution. They are then rinsed with distilled water, soaked several days in ethyl alcohol, dried, and stored in a dust-free box. A small drop of blood from a fresh stab incision on the finger or lobe of the ear is picked up with a clean cover slip (No. 0). The glass is inverted and allowed to fall on a microscopic slide on which an alcoholic solution of neutral red and Janus green has dried. When the blood has spread between the two surfaces to form a thin film, the cover slip is rimmed with petroleum jelly. The preparation is kept at 10 to 15° C. until just before examination, when it is allowed to come to room temperature.

In order to obtain adequate uptake of the dyes by the leucocytes, it has been necessary to use much stronger solutions of stain than those recommended in the literature.² The dye solution used in this laboratory consists of 4.0 ml. of a saturated alcoholic solution of Janus green and 16.4 ml. of a saturated alcoholic solution of neutral red dissolved in 100 ml. of absolute ethyl alcohol freshly prepared by the sodium phthalate method.³ The alcoholic solution is allowed to flow onto clean microscopic slides and the excess is wiped off immediately. The slides are dried and stored in light-proof, dust-free containers. Freshly stained slides are prepared every forty-eight hours. Presumably, the intensity of scattered sunlight at this altitude (7,300 feet above sea level) modifies the dyes in an unknown manner which makes necessary the use of higher concentrations of staining solutions. The appearance of the cells and

Fig. 3.—Photomicrograph (magnification $\times 1200$) of a supravital preparation of blood cells of a subject exposed to ionizing radiation. There are fifteen refractive neutral red bodies in the lymphocyte at the center of the picture, of which only a few can be seen at this focus. One refractive body is clearly seen at one o'clock. The apex of the V-shaped shadow at three o'clock is formed by a cluster of five refractive neutral red bodies. The remainder of this shadow is composed of mitochondria and three neutral red bodies, all of which are partly out of focus.

Fig. 4.—Photomicrograph of same field as shown in Fig. 3, through phase optical system (1.8 mm. oil immersion objective with integral diffraction plate, type 1B-0.25). All of the fifteen refractive bodies in the lymphocytes can be identified in this picture because of the great depth of focus of the phase microscope. Note the deep shadows cast by the cluster of refractive bodies at three o'clock and by the single body at one o'clock seen in Fig. 3. The light shadow extending from eight o'clock to eleven-thirty o'clock is produced by mitochondria.

Fig. 1.—Photomicrograph (magnification $\times 1200$) of a supravital preparation of blood cells of a subject recently exposed to small repeated doses of radiation. Refractive neutral red bodies are seen at five-thirty and nine-thirty o'clock in the lymphocyte at the center of the print. The cluster of shadows between the two bodies are mitochondria.

Fig. 2.—Photomicrograph (magnification $\times 1200$) of a supravital preparation of blood from a subject after exposure to small doses of gamma rays for a period of two months. There are fifteen refractive neutral red bodies in the lymphocyte, some of which are almost out of focus. The large shadow at three o'clock is formed by two refractive bodies. The other shadows in the cytoplasm are produced by mitochondria.

uptake of dye by leucocytes resulting from the use of slides prepared with these strong solutions do not differ in any way from that observed in other laboratories where more dilute solutions of supravital dyes are employed.

RESULTS

It was observed that the lymphocytes of persons exposed to ionizing radiations and toxic chemicals contained more refractive neutral red bodies than did the cells in the blood of unexposed subjects. These bodies, previously described in normal lymphocytes by Gall,⁴ were irregularly placed throughout the cytoplasm. They were irregular in shape, varied considerably in size, and had a more decided brick-red color than did the neutral red-staining vacuoles (Figs. 1 to 3). There was no increase in number or size on standing twelve hours at 10 to 15° C. The number of refractive bodies per cell varied from zero to more than thirty. The refractiveness of these bodies resembles that of the granules in cells of the granulocyte series and distinguishes them from vacuoles and nonrefractive bodies which also stain with neutral red dye.

Examination of the same blood samples stained with Wright's, Giemsa's, and peroxidase stains revealed no morphologic abnormalities of the lymphocytes similar to that described.

By using contrast microscopy, additional information was gained about the structure of the refractive neutral red bodies. If individual cells in a supravital preparation were examined first through an ordinary microscope and then through a phase microscope, it was observed that the refractive neutral red bodies showed a high phase contrast while the nonrefractive and vacuolar neutral red-staining bodies showed a low phase contrast (Fig. 4). This indicates that the density of the neutral red bodies is high and that they probably exist in the solid or granular phase. The mitochondria are the only other structures in the lymphocytes that show a high phase contrast. These bodies are not easily confused with the neutral red bodies under the contrast microscope since they are smaller and their green color is poorly transmitted through the phase optical system, while the red color of the refractive bodies is well transmitted.

The increase of the neutral red bodies in the lymphocytes of the exposed groups represents essentially a quantitative rather than a qualitative change. The modification in the numbers and distribution of neutral red bodies in lymphocytes for subjects variously exposed to radiation is shown in Fig. 5. In order to facilitate the demonstration of lymphocytic changes of this nature, it was decided to differentiate between cells which contained an abnormally large number of refractive neutral red bodies and those which did not. It was agreed, therefore, on a completely arbitrary basis, to designate any lymphocyte with five or less neutral red bodies as "normal" and to consider any cell with six or more bodies as "abnormal." This terminology will be used in the remainder of this article.

One thousand sixty-four hematologic studies on 364 subjects have been analyzed. Fig. 7 is a scatter diagram showing the percentage of abnormal lymphocytes in all subjects divided into control and exposure groups. The explanation of the type and degree of exposure of each group is given in Table I.

TABLE I. TYPE AND DEGREE OF EXPOSURE OF GROUPS MENTIONED IN SCATTER DIAGRAMS

GROUP	NUMBER OF PERSONS IN GROUP	DESCRIPTION OF WORK	DEGREE OF EXPOSURE
Group A			
Unexposed			
Class I			
Military personnel	62	Physical work out- of-doors	None
Civilian personnel	40	Indoor work ranging from clerical and administrative jobs to theoretical scientific work	None
Ambulatory clinic patients with upper respiratory infection	8	Varied	None
Class II			
Laboratory technicians and scientists	10	Laboratory work	None, but incidental exposure to radiation cannot be excluded completely
Skilled craftsmen	49	Plumbing, carpentry, electrical work, and machine shop work	No known exposure to radiation; plumbers exposed to lead oxide fumes within tolerance limits; machinists exposed to metal fumes
Group B			
External radiation			
Class I			
	25	Laboratory work	Incidental exposure to external radiation; average exposure less than 0.3 to 0.5 r per month
Class II			
	41	Laboratory work	Intermittent exposure chiefly to natural sources; average exposure 1 r per month or less
Class III			
	25	Laboratory work	Consistent exposure chiefly to radiation from accelerating equipment (cyclotron, Van de Graaff, etc.); average exposure 1.5 r per month or less; rarely did dose in any given day approach 0.1 r
Class IV			
	22	Laboratory work	Consistent exposure over six-month period to strong radioactive sources; monthly exposure 3.0 r or less, with certain persons exceeding this value for a single month; daily exposures frequently exceeded 0.1 r and occasionally reached 0.5 r
Group C			
Radioactive material A			
Class I			
	8	Laboratory work	Contact with radioactive material A, an alpha particle emitter; no deposition of material within body according to reasonably sensitive tests

TABLE I—CONT'D

GROUP	NUMBER OF PERSONS IN GROUP	DESCRIPTION OF WORK	DEGREE OF EXPOSURE
Class II	17	Laboratory work	Contact with radioactive material A; some deposition of material in the body, but average amount below maximum permissible value
Radioactive material B Class I	29	Laboratory work	Contact with radioactive material B, an alpha particle emitter; no deposition of material in the body according to moderately sensitive test
Class II	6	Laboratory work	Contact with radioactive material B; deposition of material in the body approaching maximum permissible amounts
Group D Uranium	20	Laboratory and plant work	Mild to moderate exposure to uranium chiefly as oxide fumes

This exposure refers to the period 1943 to 1946 and does not take into consideration the previous exposure record of the subject. In practically all cases except those in Radiation Groups II and III, previous exposure to toxic chemicals or radiation was negligible. Each point in the scatter diagram represents the percentage of abnormal lymphocytes for a single subject. In the case of most of the controls, this point is based on one examination; in the case of the exposed subjects, the point represents the average of many (in one instance, thirty) examinations. Where radiation exposure was intermittent it was impossible to correlate the time of the hematologic examinations with the time of the exposure. For purposes of comparison, Figs. 6, 8, 9, and 10 show scatter diagrams of the total white blood count, the total abnormal lymphocyte count, the total lymphocyte count, and the percentage of lymphocytes in the differential white blood cell count for each exposure group. As in the case of Fig. 7, each point represents an average figure for all examinations on a single individual.

Figs. 11 and 12 show the increase in percentage of abnormal lymphocytes in persons accidentally exposed to single, large, instantaneous bursts of general body radiation. It is unfortunate that previous determinations of the percentage of abnormal lymphocytes were not made on these subjects. A complete hematologic report of these cases will be presented in a forthcoming article. Single exposures to general body gamma radiation which did not exceed 5 roentgens and which were delivered over a period of several hours produced no increase in the percentage of abnormal lymphocytes.

Similar increases in abnormal lymphocytes have been observed in rabbits and cows exposed to large doses of ionizing radiation. Morphologic changes of this type in the lymphocytes of mice and rats exposed to radiation could

Fig. 5.—This chart arranges the lymphocytes of representative individuals in various exposure groups according to the number of refractive neutral red bodies which they contain. The bands extending across the page represent 100 per cent of the lymphocytes for an individual. The scale of fraction of the lymphocytes is shown at the bottom of the chart. The numbers in each segment of a band denote the number of refractive bodies in that fraction of the lymphocytes containing more than five bodies. The lymphocytes containing more than five bodies are lumped together in one group designated by a plus sign. Thus, in Case A, Group A, 10 per cent of the lymphocytes contained no neutral red bodies; 25 per cent, one body; 8 per cent, two bodies; 2 per cent, three bodies; and 5 per cent, five bodies.

INCREASE IN REFRACTIVE NEUTRAL RED BODIES IN LYMPHOCYTES AFTER ACUTE EXPOSURE

Fig. 11.—Chart showing the percentage of abnormal lymphocytes in four subjects exposed to an instantaneous burst of total body radiation. All subjects showed high initial total leucocyte counts, but subsequent changes in the blood counts indicated evidence of mild transient bone marrow injury only in Cases I and II.

INCREASE IN REFRACTIVE NEUTRAL RED BODIES IN LYMPHOCYTES AFTER ACUTE EXPOSURE

Fig. 12.—Chart showing the percentage of abnormal lymphocytes in two subjects receiving brief exposure to large doses of ionizing radiation. Case V received a lethal amount of radiation. Case VI was exposed to a relatively small dose of radiation which produced no other changes in the blood picture.

not be detected because the large amounts of neutral red dye normally taken up by the cytoplasm of the lymphocytes interferes with the identification of the refractive bodies.

DISCUSSION

A survey of the literature has failed to disclose previous descriptions of similar morphologic changes in lymphocytes after *in vivo* exposure to small repeated doses of ionizing radiation. Morphologic changes in living cells of various kinds have been reported following exposure to single large doses of radiation. Prigosen⁵ has reported the appearance of neutral red bodies in irradiated tumor cells. Recently Schrek⁶ described an increase in cytoplasmic vacuoles in dark-field preparations of lymphocytes after *in vitro* and *in vivo* exposure to x-rays.

Inspection of the scatter diagrams in this report shows that there is an increase in abnormal lymphocytes in the persons exposed to ionizing radiation. The percentage and total number of abnormal cells can be correlated with the magnitude of chronic exposure. The significance of the data presented in these diagrams is evident without further statistical treatment. There are several features of these diagrams, however, which require further discussion.

A significant difference between the controls (Group A, Class I) and the groups exposed to radiation (Group B, Classes I, II, III, and IV) was observed only for total leucocyte count, the proportion and absolute numbers of abnormal lymphocytes. In the case of the total white blood cell count, the difference can be demonstrated by comparing the average counts for each group. Since most of the total counts of all groups lie between 5,000 and 9,000 cells per cubic millimeter, however, the value of any individual count has little significance in determining the exposure group into which the subject falls. On the other hand, the difference in the percentage of abnormal cells and absolute abnormal cell counts between control and exposed subjects is reflected in the value for an individual subject. Most of the controls have less than 20 per cent abnormal cells or 400 abnormal cells per cubic millimeter, while all of the more consistently exposed subjects show percentages and total numbers of abnormal cells above these levels. There is so little overlap of points for exposed and control groups that the appearance of few or many abnormal cells has more than chance significance in determining the exposure of any given individual.

A difference in percentage and absolute numbers of abnormal lymphocytes also exists between the controls and the groups exposed to certain chemicals. In this respect, it should be emphasized that the biologic action of natural uranium is due to its chemical rather than its radioactive properties. Thus the increase in percentage of abnormal lymphocytes in Group D is probably related to the chemical effect of uranium. The increase in percentage of abnormal cells in Group A, II (Fig. 7) is added evidence pointing to the fact that exposure to toxic chemicals changes the percentage and the absolute number of abnormal cells, since nine of the fourteen points above the 20 per cent abnormal cell level represent plumbers who were frequently exposed to lead fumes. These subjects have shown no clinical or laboratory evidence of plumb-

ism except for an occasional mild degree of basophilic stippling of the red blood cells. An increase in abnormal lymphocytes was also found in persons working with industrial nonradioactive chemicals besides uranium and lead.

It is evident from Figs. 11 and 12 that exposure to a single large dose of ionizing radiation increases the proportion of abnormal cells in the circulating blood. The response of the lymphocytes of the four subjects in Fig. 11 is essentially the same, although the radiation dosage of the subjects differed by a factor of ten. It must be concluded, therefore, that the increase in abnormal lymphocytes is not proportional to the dosage when administered as a single brief exposure.

SUMMARY

1. Analysis of the total leucocyte counts of persons chronically exposed to ionizing radiation and toxic chemicals shows a significant statistical decrease in the exposed groups.

2. Analysis of the absolute number and of the percentage of lymphocytes in the differential counts of the same persons shows no significant change.

3. Morphologic study of supravital preparations of blood cells of persons chronically and acutely exposed to ionizing radiation indicates a striking increase in the number of refractive neutral red bodies in the cytoplasm of the circulating lymphocytes. An increase in neutral red bodies is also found in persons working with toxic chemicals.

4. These neutral red bodies have high density and may be considered to be granules. They have not been identified in fixed preparations.

STUDIES ON LYMPHOGRANULOMA VENEREUM: EVALUATION OF THE COMPLEMENT FIXATION TEST WITH LYGRANUM

MORRIS F. SHAFFER, PH.D.,* AND GEOFFREY RAKE, M.B., B.S.
NEW BRUNSWICK, N. J.

IN THE development of our knowledge of most infectious diseases, progress has been expedited by improvements in the methods available for diagnosis, particularly in the case of latent infections or in the frank disease when symptomatology and clinical signs are not distinctive. Thus in lymphogranuloma venereum Frei's discovery¹ of the intradermal sensitivity of infected individuals to lymphogranulomatous bubo pus constituted a great advance since it enabled a diagnosis to be made on grounds other than the clinicopathologic basis set forth by Durand, Nicolas, and Favre.² By means of this cutaneous reaction a variety of lesions other than those of the genitals and regional lymph nodes were linked to a common background of lymphogranulomatous infection; in some instances it has been possible later to confirm the diagnosis by the actual isolation of the etiologic agent from pathologic material.³ Until recently, however, a serious deterrent to the routine use of the Frei test in large-scale investigations (which are highly desirable for a more complete understanding of the epidemiology of the disease) was the fact that to the great majority of clinicians there was not readily available human bubo pus of satisfactory specific activity and free from contamination with antigens derived from other infectious organisms.

Several preparations of tissues experimentally infected with virus, such as brain tissue from different animal species,⁴ have been suggested and employed as a substitute for human bubo pus. These, while containing sufficient specific antigen to elicit a positive Frei reaction, also include relatively large amounts of foreign tissue which may evoke a nonspecific inflammatory response. This makes interpretation of the test difficult unless it is compared with the result of simultaneous inoculation of normal tissue emulsion as control. Furthermore, allergic hypersensitivity to the accompanying brain tissue, whether inherent in the individual or acquired only after repeated skin testing, may sometimes obscure any specific reaction to the virus antigen.⁵ It should be pointed out, however, that while no control material is inoculated in tests with human bubo pus and any reaction following its introduction is taken as evidence of a positive response, there is little reason to believe that the skin of occasional individuals may not be irritated by injection of certain components of such pus irrespective of the presence of, and reaction to, lymphogranuloma antigen.

A new and improved reagent (Lygranum) for the Frei test⁶ has been developed as a result of the observation that the etiologic agent of lymphogranuloma venereum will proliferate luxuriantly when introduced into the

yolk sac of the embryonated hen's egg.⁷ The enormous numbers of elementary bodies and other developmental forms of the virus⁸ thus obtained have been readily separated from the bulk of the host tissue by differential centrifugation, and the infective properties suitably destroyed while preserving the antigenic activity. In the experience of several groups of investigators⁹ the results have been eminently satisfactory, with this purified suspension of virus showing diverse features of superiority over mouse brain antigen and being at least equal in the number of positive reactors detected when compared with highly potent samples of human pus. The concentration of antigen in Lygranum preparations can be controlled, so there is no prevailing reason why it should not be available in a form even more potent than the most active specimens of bubo pus. There has been some criticism of Lygranum because of difficulty in interpreting so-called "nonspecific" reactions,¹⁰ consisting largely of erythema without papule formation or, less frequently, small papules elicited in nonlymphogranulomatous persons. It should be emphasized again, that the zone of erythema seen at the site of inoculation of Lygranum S. T. is of no diagnostic significance whatever. Only the presence of a *definite papule of at least 6 mm.* in diameter should be taken as indicating a positive reaction with Lygranum, and *every test should be controlled* with normal yolk sac material injected simultaneously with the specific antigen. The control injection usually provokes a negligible or trivial reaction, but individuals who are sensitive to chick embryo materials may give papules with the control from normal yolk sac as large as those with Lygranum; in such persons the reaction to Lygranum S. T. should not be considered as positive.

The utility of Lygranum is not limited to the intradermal test for it has also been found potent in the detection of complement-fixing antibodies in the serum.¹¹ While the evidence thus far acquired has shown Lygranum to be a very sensitive indicator when used in this manner as an aid in the diagnosis of infection with lymphogranuloma virus, other studies have demonstrated that cross reactions are obtained with this antigen in complement fixation tests on the sera from patients with trachoma or inclusion blennorrhoea¹² and in certain cases of atypical pneumonia or pneumonitis due to psittacosis or closely related viruses.^{13, 14} This is not unexpected since, in spite of obvious differences in modes of transmission and tissue tropisms, the agents responsible for these diseases appear to share many properties, including the possession of a common antigenic factor.^{14, 15} It is one of the purposes of this paper to explore the limits of the specificity of Lygranum in the complement fixation test in the light of a comprehensive summary of our experience with several hundred sera derived from persons with a variety of clinical conditions.

REAGENTS AND TECHNIQUE

Antigens.—Egg-adapted lymphogranuloma virus was employed as inoculum for six- or seven-day chick embryos via the yolk sacs; the latter were harvested shortly prior to, or immediately following, death of the embryo from specific infection, all embryos being candled twice a day. Those yolk sacs, found on examination to contain abundant virus in the absence of other agents cultivable on artificial media, were pooled and ground or shaken with

ten volumes of physiologic saline. For the tests to be reported here, the virus was freed from most tissue material by differential centrifugation and finally suspended in saline containing 0.1 per cent formalin.¹¹ Control material was prepared from normal yolk sacs in exactly the same fashion. Nigg has found that a useful antigen may be obtained by the simple expedient of treating the crude saline suspension of virus-infected yolk sac with urea or ether.¹⁶ Recently a combination of boiling and treatment with phenol has proved even more satisfactory¹⁷; not only may the specific complement-fixing activity of the antigen be enhanced thereby, but also yolk sac preparations treated in this way do not show the non-specific fixation with sera from cases of early syphilis (see below). The mechanisms involved are not understood.

In some of the early tests we employed in place of yolk sac virus the supernate obtained by centrifugalizing at low speed a saline suspension of lymphogranulomatous mouse lungs,¹⁸ together with control material from similarly treated normal mouse lung. The results with the two viral antigens were entirely in agreement; we preferred later to use yolk sac antigen since it was more readily available in large amounts, was usually somewhat more potent, and could readily be obtained free from contamination with other organisms. The lungs of mice may contain varying numbers of adventitious bacteria or other agents which might lead to erroneous results, although we have experienced no difficulty from this cause. Finally the handling of intranasally infected lymphogranulomatous mice constitutes a definite hazard in the laboratory.¹⁹ The soluble antigen found in Seitz filtrates of virus-infected yolk sac or mouse lung tissue²⁰ has also been utilized, but this may be less potent than suspension-containing particulate virus.

For use in complement fixation tests stock antigen from any of the sources mentioned was adjusted by dilution so that it was not anticomplementary, gave definite reactions with known weakly positive lymphogranulomatous sera, and gave no reaction with sera from normal individuals.

Sera.—Just before use the sera were inactivated for twenty minutes at 56 or 60° C.; the higher temperature was helpful in reducing the anticomplementary behavior observed on prolonged storage of serum.²¹ Serial doubling dilutions were made in physiologic saline. In most cases the lowest initial dilution of serum tested was 1:2, although on a few occasions the undiluted serum was also used. Since during fixation the serum is acting in a final dilution three times that originally introduced, we have recorded the titers as the highest final dilution giving definite specific fixation.

Complement.—Guinea pig serum was used, either fresh or stored at -32° C. until needed; it was titrated and diluted just before use. Two units in 0.2 ml. were usually obtained with a 1:20 to 1:30 dilution.

Performance of Test.—The following procedure was found to yield satisfactory results while retaining features of simplicity and convenience, permitting the test to be read within two hours after it was prepared. To a series of tubes was added 0.2 ml. of each of the reagents, in the order stated: diluted patient's serum, 2 units of hemolytic complement, specific antigen. A control series was set up in each instance with normal tissue material in place of the specific antigen. In every test controls were also included to exclude anticomplementary or hemolytic action of the antigen or patient's serum, as well as to demonstrate the activity of the complement. After incubation for seventy-five minutes in a 37° C. water bath, to each tube was added 0.2 ml. of the indicator. This volume contained a 3 per cent suspension of sheep corpuscles in saline and 2 units of amboceptor, the cells having been sensitized beforehand by incubation for thirty minutes at 37° C. Readings for fixation (inhibition of hemolysis) were made after thirty minutes longer at 37° C. Only when all controls were satisfactory was a test considered of possible diagnostic significance. The sensitivity of the test can be increased somewhat by carrying out fixation in the refrigerator overnight or by a short period of incubation in the cold following that at 37° C. Prolonged fixation in the cold increases the tendency to nonspecific fixation with normal yolk sac control material, however, so this refinement was used only rarely.

Nearly all sera were tested in serial dilutions at least twice, and the majority were tested several times to check the reproducibility of results. One additional point should be

mentioned here, namely, the desirability of testing serum specimens with reasonable promptness after their collection. If fluid sera are stored without preservative in the refrigerator for many months they frequently suffer deleterious bacterial or fungous contamination; furthermore, the specific titer tends to diminish with aging while the anticomplementary properties increase, making it difficult or impossible to test satisfactorily low dilutions of the serum. This should be borne in mind, since some sera are of low titer even when tested shortly after their withdrawal from the donor.

PRESENTATION AND DISCUSSION OF EXPERIMENTAL DATA

1. *Tests on Sera from Persons With History or Signs of Overt Lymphogranulomatous Infection and Positive Frei Test.*—We have tested serum specimens from 149 patients falling in this classification, with the results summarized in Table I.

TABLE I. COMPLEMENT FIXATION TESTS ON SERA FROM PERSONS WITH EVIDENCE OF LYMPHOGRANULOMATOUS INFECTION

TYPES OF LESIONS OBSERVED IN PATIENTS	NUMBER TESTED	LYGRANUM COMPLEMENT FIXATION	
		POS.	NEG.
Genital and/or inguinal lesions*	33	33	0
Posterior bowel lesions†	61	60	1
Other lesions‡	55	54	1
Total	149	147	2

*This group includes early or chronic lesions of genitals and/or inguinal adenopathy.

†This group includes: (1) proctitis and/or rectal stricture; (2) other anal lesions such as sinus, fistula, etc.; (3) involvement of colon.

‡This group includes cases presenting one of the following: (1) both genitoinguinal and rectal pathology, (2) generalized systemic manifestations, (3) laboratory infections, (4) other lesions not further classified.

An analysis of the data has brought out certain points of interest. In our hands the complement fixation test gave positive results with the sera from 98.6 per cent of 149 individuals in whom the Frei reaction and history or clinical signs were indicative of overt lymphogranulomatous infection; the two failures may have been due to a very low concentration of antibodies which could perhaps have been detected by making the conditions of testing more sensitive, or to the absence of antibodies in these particular serum specimens.

The titers of the positive sera ranged from 6 to 1,920 and greater. The frequency with which various titers were encountered was as follows:

		TITER
32	(21.8 per cent)	6 to 15*
40	(27.2 per cent)	30 to 60
42	(28.5 per cent)	120 to 240
33	(22.4 per cent)	480 or greater

The data have been examined in an attempt to ascertain the factors influencing the complement-fixing titers obtained.

1. *Activity Status:* Usually, but not invariably, the sera of patients with clinically active lesions showed higher titers than the sera of patients with healed lesions.²²

2. *Intensity of Frei Reaction:* The sera of individuals who yielded a large cutaneous response usually showed higher titers than those from persons whose Frei reactions were weak (see also Grace and Rake²²). In some instances, however, patients with antibodies of

*It should be recalled that all figures concerning titer are given at threefold the usual designation in the literature. Thus most authors would give these titers as from 2 to 5.

low titer (6 to 15) gave skin reactions of greater intensity and extent than other persons whose serum titer was tenfold greater.

3. *Duration of Infection:* In recent infections the titers ranged from 6 to 960; where the disease had been in progress for three to eight years the titers observed were from 60 to 960. A patient with infection of ten years' standing was found to have a titer of 30; another whose disease dated back fifteen years showed a titer of 90, while the serum of a third individual twenty years after the onset of inguinal adenopathy showed a titer of 6. Thus the duration of infection was not necessarily reflected in the titer.

4. *Location of Lesions:* No obvious disparity in regard to antibody levels was noted between infections characterized by inguinal adenopathy and/or genital lesions and those involving the posterior regions of the bowel.

5. *Sex:* In the respective sexes the serum titers were distributed as follows:

TITER	WOMEN	MEN
6 to 15	8	24
30 to 60	6	25
120 to 240	15	24
480 or greater	4	8

While these figures indicate that titers of 120 or greater were more common in women, the number of cases involved is too small to be statistically significant.

6. *Race:* The titers in whites and Negroes were closely parallel, that is:

TITER	WHITES	NEGROES
6 to 15	19	13
30 to 60	16	15
120 to 240	21	18
480 or greater	7	5

7. *Concomitant Venereal Infection:* The presence of other venereal diseases did not noticeably affect the lymphogranuloma complement-fixing titer. It is noteworthy that in the group with rectal lesions (chiefly stricture and/or proctitis) thirty-five had no history or evidence of other venereal disease, twenty had signs, serologic evidence, or history of syphilis, and one had a history of gonorrhea. In the genitoinguinal group, eight had no evidence of other venereal disease, nine had a history of syphilis, and three had other venereal infections.

Discussion: It should be emphasized that in developing the complement fixation test with lymphogranuloma antigen, the results and technique were adjusted in an effort to set up conditions which would permit the detection of antibody in weakly reactive lymphogranulomatous sera. With the method adopted, specific fixation was obtained with the sera of 98.6 per cent of 149 clinically lymphogranulomatous, Frei-positive patients. In eleven of these the titer was only 6, and if the lowest initial dilution of serum tested had been 1:5 instead of 1:2, the demonstration of antibody would have failed. The importance of employing low as well as high dilutions of serum is thus evident, although Dulaney and Packer,²³ who in 97 per cent of their series of thirty-three clinically lymphogranulomatous patients obtained fixation with Lygranum in initial serum dilutions of 1:40 or greater, feel that a 1:20 dilution (corresponding to our titer of 60) should be considered as the lower limit for good serologic evidence of infection with the causative virus.

Several other workers have reported the results of complement fixation studies with Lygranum. Using a method similar to ours, Levine, Holder, and Bullowa²⁴ obtained fixation

with the sera of each of eleven known lymphogranulomatous patients and with the sera of eighteen other patients without overt lymphogranuloma venereum who yielded positive or doubtful-Frei tests. Blair²⁵ similarly obtained fixation with the sera of four patients showing clinically characteristic lymphogranuloma and thirteen other patients without history of the disease who had positive Frei reactions. A less favorable report was published by Knott and co-workers²⁶ who obtained positive tests by complement fixation in 75 per cent of a group of thirty-one patients diagnosed clinically as lymphogranulomatous. From their data it is doubtful whether all of the cases in the group represented true lymphogranulomatous infection. Only 84 per cent of their patients gave positive Frei tests and 45 per cent showed positive Ito-Roenstierna tests; in some of the patients the duration of the lesions was only three days. Also contributory to the failure of Knott and associates to obtain a higher percentage of positive results may be the fact that in their serologic tests complement was used at 1:10 dilution, a concentration two to three times greater than that which we employed, which might well reduce the sensitivity of the test so that it would fail to detect weakly reactive sera such as we found in 7.4 per cent of our lymphogranulomatous series.

Howard and co-workers²⁷ tested seventy-six patients with positive Frei reactions; the sera of seventeen gave negative complement fixation tests. The authors state that in this group ". . . in most instances there was a history suggesting infection with lymphogranuloma venereum in the remote past . . . there was no clinical evidence of infection at the time the tests were made; skin sensitivity alone remained." Unfortunately the details of the serologic technique employed in their study are not stated, making it difficult to evaluate the sensitivity of the method.

Recently Florman²⁸ has published the results of a series of tests with Lygranum antigen, employing a modified micro-Kolmer hemolytic system. His data indicate that this method was relatively insensitive for detecting weakly reacting sera, since in a series of parallel determinations on twelve sera he obtained nine positives using the method we have recommended, while only seven showed fixation when tested by his routine technique. Furthermore, in a group of eighteen patients with positive or doubtful Frei tests he obtained only eight positives by complement fixation, a far smaller proportion than that obtained by any of the others who have compared the cutaneous and serologic tests.

2. *Correlation of Complement Fixation Titer and Serum Protein Levels in Persons With Lymphogranuloma.*—Nicolas-Favre disease is frequently accompanied by the development of hyperglobulinemia and it has been suggested²⁹ that this might be due to the increased production of specific antibodies. So far no direct experimental evidence has been obtained in support of the hypothesis, since the sera of lymphogranulomatous patients usually exhibit only slight virus-neutralizing properties which make quantitative evaluation difficult. It is conceivable, however, that the increased globulin values seen in lymphogranuloma reflect the production of considerable amounts of antibody which react in the complement fixation test but are not effective in virus neutralization. An opportunity to examine the problem from this angle was afforded by Dr. Marion Howard, who furnished a number of such sera together with data on their values for globulin and their albumin: globulin ratios. Table II summarizes the results of our complement fixation tests on a group of sera which were tested within a few months of their collection from the patients, together with Dr. Howard's data on the protein values. We have not included the data on several other sera which were tested after two or more years' storage in the refrigerator.

TABLE II. LYGRANUM COMPLEMENT FIXATION TITERS AND PROTEIN VALUES OF LYMPHOGRANULOMATOUS SERA

F. S.	960	5.42	0.72

It was found that the globulin values showed little deviation from the normal range in those patients whose sera had only low complement-fixing titers (6 to 15), whereas in six of eight patients with serum titers of 30 or greater, the globulin content was above 3 Gm. per 100 ml. serum; the maximum globulin values were obtained with sera which showed high complement-fixing activity. Our limited data, therefore, indicate positive correlation between elevation of the serum globulin and the titer of complement-fixing antibody versus lymphogranuloma antigen in patients with Nicolas-Favre disease.

3. *Tests on Sera from Persons Infected with Certain Viruses Related to the Agent of Lymphogranuloma Venereum.*—Data previously published¹² showed that the sera of patients with trachoma fixed complement specifically in the presence of lymphogranuloma virus antigens. We have now had the opportunity, through Dr. Phillips Thygeson, to test sera from thirty trachomatous individuals. Five of the sera were anticomplementary due to prolonged storage before testing; another patient's serum gave nonspecific fixation with normal yolk sac control material. Twenty-one of the remaining twenty-four sera fixed complement specifically in the presence of lymphogranuloma antigens prepared from elementary body suspensions sedimented by high-speed centrifugation, or the soluble antigen obtained in Seitz filtrates, or both. The titers were usually low and more readily demonstrable by fixation overnight in the refrigerator. Complement fixation was demonstrable with the sera from three of four patients who had shown clinical healing under the influence of sulfonamide therapy. Despite the presence of complement-fixing antibodies in their sera the Frei test was uniformly negative whenever performed on trachomatous patients.

Sera from seven patients with psittacosis were obtained through Dr. K. F. Meyer,* who also furnished the results of complement fixation tests carried out with psittacosis antigen in his laboratory. Each of the sera showed strong complement fixation with Lygranum antigen, our titers ranging from 120 to 1920.¹³

*The Hooper Foundation, San Francisco, Calif.

Complement fixation with both lymphogranuloma and psittacosis antigens was also demonstrable with each of the sera from seven patients with virus pneumonitis which was presumed or proved due to an agent related to the meningopneumonitis virus of Francis and Magill.³⁰ Six of these sera¹³ were obtained from Dr. M. D. Eaton;* the seventh specimen was furnished by Dr. John H. Dingle.† These seven sera gave titers ranging from 6 to 60 when tested with Lygranum.

Through Dr. Thomas P. Magill‡ sera were also obtained from eleven patients with "atypical pneumonia" where there was no evidence to incriminate as etiologic agents any members of the psittacosis-lymphogranuloma group of viruses. None of these sera gave fixation with Lygranum.

Discussion: Complement fixation tests on the sera of patients infected with various viruses of the psittacosis-lymphogranuloma group have shown that these agents must share a common antigenic factor which stimulates the production of antibodies responsible for cross reactions within the group. The definite, albeit weak, reactions we observed when trachomatous sera were tested with lymphogranuloma antigen served to re-emphasize the close biologic relationship between these two etiologic agents which was previously predicated on the basis of striking similarities in morphology, staining, intracytoplasmic growth, and other characteristics. Unfortunately, trachoma viral antigen was not available for reciprocal tests with lymphogranulomatous sera.

Cross reactions of high titer have been demonstrated repeatedly^{13, 14b, 15, 17c, 24} for human psittacotic and lymphogranulomatous sera not only when they are tested with antigens from either of these viruses, but also in the presence of antigens derived from the viruses of meningopneumonitis³⁰ and mouse pneumonitis.³¹ Differences have been noted in the titers of individual sera versus the respective viral antigens used for testing, but these may have been due, in part at least, to varying potency of the antigens and to differences in the techniques of testing employed in the several laboratories. Smadel, Wertman, and Reagan^{14b} have shown in this connection that the sera of patients with either psittacosis or lymphogranuloma venereum usually give complement fixation to approximately the same titer when tested simultaneously with standardized antigen from the heterologous or homologous virus.

The sera of various animal species infected or immunized with members of the psittacosis-lymphogranuloma group of agents show differing degrees of specificity in complement fixation tests with the several viral antigens. The situation is not entirely clear in regard to the serologic response of pigeons, which often acquire ornithosis naturally.^{32a} Although the sera of birds convalescent from enzootic or epizootic ornithosis have been reported not to give fixation with Lygranum,^{14b, 32b} two of three pigeon sera sent us by Dr. K. F. Meyer did, in fact, give strong fixation with this antigen (titers 120 and 480, respectively).¹³ Further, Beck and co-workers^{15b} found in three of four pigeons infected with the S-F strain of human pneumonitis virus a slight rise in antibodies to lymphogranuloma venereum antigen.

Several serologic studies have been carried out among persons with pneumonitis or atypical pneumonia where no direct contact with infected birds was known. Eaton and colleagues investigated two groups of such cases. In one small series an agent related to

*The California Department of Health, Berkeley, Calif.

†The Thorndike Laboratory, Boston City Hospital, Boston, Mass.

‡Cornell University Medical College, New York, N. Y.

the viruses of meningopneumonitis and psittacosis was incriminated as etiologic agent.^{32a} These patients all showed antibodies reacting indiscriminately with psittacosis, meningopneumonitis, lymphogranuloma, and mouse pneumonitis antigens; in several instances the development of a rise in titer for these antigens during the course of the illness was demonstrated.^{14a} It may be noted here that in the case of another member of the psittacosis-lymphogranuloma group of viruses, namely, that causing an epidemic of severe pneumonitis in the bayou region of Louisiana, serum specimens from a few patients who had been infected showed fixation not only with antigen from the specific etiologic agent, but also with preparations from other viruses in the related group.^{32b} In a second, larger series of cases of pneumonitis of unknown etiology which were studied by Eaton and Corey the sera of roughly 10 per cent of the patients showed a fourfold or greater increase in titer versus these antigens during convalescence when compared with samples collected during the acute phase.^{11a} Smadel^{14c} examined the sera of forty-five cases of atypical pneumonia drawn from several large urban centers of eastern United States. Ten cases were believed to be due to psittacosis; five other cases were considered on the basis of complement fixation tests possibly to be of psittacotic origin, but the sera of these patients showed no significant increase in titer during the course of recovery from the disease.

Dingle and associates,³⁴ in their extensive studies on atypical pneumonia, encountered six patients with respiratory disease from whom strains of virus resembling the agent of meningopneumonitis were isolated in the laboratory of Dr. Thomas Francis, Jr.* During the course of illness none of these six showed any rise in the titer of antibodies reacting with the agent of meningopneumonitis, whereas five other patients with respiratory infections, of whom only one showed atypical pneumonia, developed a fourfold or greater increase in serum titer during the course of illness. Complement fixation tests versus meningopneumonitis antigen were then carried out on the sera of a large group of well soldiers and patients with various respiratory infections. While positive reactions were only infrequently encountered among the sera from white donors, there was an appreciable concentration of positive reactions among the Negro group, irrespective of history of respiratory disease or evidence of atypical pneumonia. Since the Negroes were drawn chiefly from the South, where the incidence of lymphogranuloma is known to be high, it was suspected that the incidence of positive reactors among them might be due to crossreactions resulting from infection with lymphogranuloma virus.

Thomas and co-workers³⁵ made the observation that in persons with atypical pneumonia of unknown etiology sera taken during the convalescent phase frequently showed considerable complement-fixing activity versus crude mouse lung suspensions infected with any of several dissimilar viruses, including members of the psittacosis-lymphogranuloma group. These sera also reacted, although to a lesser extent, with similarly prepared suspensions of normal lungs from human beings and from mice and other laboratory animals, and with normal chick yolk sac. Acute phase sera from the same patients showed much less reactivity. It is interesting that the convalescent sera did not react with antigen of psittacosis virus propagated in tissue culture. The capacity to react with dissimilar antigens could be reduced by merely heating the sera to 60 to 65° C. or by absorption with normal mouse lung. The antigenic component responsible for fixation with atypical pneumonia sera was associated with large particles contained in the crude lung suspensions, since it could be reduced by centrifugation.

From the foregoing we conclude that: (1) antibodies reacting with Lygranum are usually demonstrable in the sera of nonlymphogranulomatous persons who are known or presumed to be infected with any one of the several other members of the group of related viruses; (2) in sera from cases of atypical pneumonia of unknown etiology, fixation versus lymphogranuloma virus is ordinarily lacking if infection with viruses of the psittacosis-lymphogranuloma group can be excluded or is highly unlikely; (3) in some cases of atypical

*University of Michigan.

pneumonia there develop during convalescence substances which react more or less nonspecifically with certain tissue components from uninfected or virus-infected lung or other tissue. These latter reactions can frequently be distinguished from specific fixation occurring with virus antigens through the use of control antigens prepared with normal tissue; they can also be reduced or eliminated by preliminary heating of the sera to 60 or 65° C., as we have done.

4. *Tests on Persons With Evidence of Syphilis.*—Complement fixation tests with Lygranum were performed on the sera of 131 individuals having evidence of syphilis. Some of the sera were specimens collected for routine premarital examinations; a large proportion was collected from patients attending venereal disease clinics. Various stages of syphilis were represented including latent, primary, secondary, and neurosyphilis. In thirty-four of the patients the syphilitic infection was congenital. Table III summarizes the results of the tests.

TABLE III. LYGRANUM COMPLEMENT FIXATION TESTS ON SERA OF PERSONS WITH EVIDENCE OF SYPHILIS

SOURCE OF INFECTION	NUMBER TESTED	LYGRANUM COMPLEMENT FIXATION		
		POSITIVE	NEGATIVE	NONSPECIFIC
Congenital	34	2*	32†	0
Acquired	97	59	30	8

*These patients were Frei-positive, married, white women.

†Thirty of these patients were also Frei tested; all gave negative reactions.

In sharp contrast to the low incidence of positive serologic or cutaneous reactions with Lygranum among those with congenital syphilis³⁰ are the findings in the group of individuals whose syphilitic infection was otherwise acquired. Forty-five of these ninety-seven were also given Frei tests. The findings are given in Table IV.

TABLE IV

LYGRANUM COMPLEMENT FIXATION	FREI REACTION	NUMBER IN GROUP
Pos.	Pos.	10
Pos.	Doubt.	3
Pos.	Neg.	18
Neg.	Neg.	7
Nonsp.	Neg.	6
Neg.	Nonsp.	1

Thirteen (29 per cent) of the forty-five persons with syphilis of noncongenital origin yielded positive or doubtful Frei tests; the sera of all thirteen fixed complement specifically in the presence of Lygranum. These individuals included five white women, five Negro men, and three Negro women; from none of them was a history of overt lymphogranuloma elicited and on examination they were asymptomatic. An additional 38 per cent of the group of forty-five gave positive complement fixation with Lygranum despite negative Frei tests.

It may be noted that the sera of eight patients with acquired syphilis showed equal fixation with normal yolk sac material and with Lygranum antigen. The significance of the various findings in the patients with syphilis as

well as in those with other genitoinfectious diseases will be discussed following the presentation of the experimental data in the next section.

5. *Tests on Sera of Persons With Genitoinfectious Diseases Other Than Syphilis.*—Complement fixation tests with lymphogranuloma antigen were performed on a limited number of sera from persons in this category, the results being summarized in Table V.

TABLE V. LYGRANUM COMPLEMENT FIXATION TESTS ON SERA OF PERSONS WITH GENITO-INFECTIONOUS DISEASES OTHER THAN SYPHILIS

DISEASE	NUMBER TESTED	NUMBER POSITIVE
Gonorrhea		
Vaginitis of childhood	5	0
Venereally acquired	19	9
Chancroid	6	3

It will be seen that roughly the same proportion of sera from persons with venereally acquired gonorrhea or chaneroid were positive versus lymphogranuloma antigen as was found for the group of syphilitic patients with acquired infection. Similarly, the failure to obtain fixation with the sera of children showing gonoeoeal vaginitis corresponds with the findings in the congenital syphilitic group. Frei tests were performed on the patients with chaneroid; one of the three whose sera showed fixation also manifested a positive cutaneous response.

Discussion: The foregoing findings among the patients with syphilis and other genitoinfectious diseases are of considerable interest. Although 61 per cent of the group of ninety-seven with acquired syphilis gave positive serologic reactions with Lygranum, many of the members of the group tested were patients coming to venereal disease clinics, and we do not consider that this figure necessarily reflects accurately the incidence which one should expect to encounter elsewhere in large-scale tests on the general population. As reported previously,^{11b} among the Negroes of the group the incidence was considerably higher in respect to positive reactions with Lygranum in both the entaneous and complement fixation tests. In the work of Dulaney and Paeker²³ it was noted similarly that among twenty-two Negro children with congenital syphilis no positive complement fixation reactions with Lygranum were obtained, whereas with sera from adults with neurosyphilis this serologic test was frequently positive and again the incidence of such reactions was definitely higher among Negroes than among whites.

Knott and colleagues²⁶ have also reported the study of a group of patients with early clinical syphilis, chiefly Negroes, attending the venereal disease clinic at the Johns Hopkins Hospital. Forty-three of the seventy-eight cases were given cutaneous tests with human Frei antigen; thirteen responded with positive or doubtful reactions. This is in surprisingly close agreement with our findings of thirteen positive or doubtful cutaneous reactions among forty-five syphilitic patients tested with Lygranum. Twenty-three of seventy-eight in the Johns Hopkins series gave complement fixation with Lygranum only; an additional thirty-four showed fixation with normal yolk sac material as well as with Lygranum. The Baltimore workers regarded as positive results all complement fixation reactions occurring with Lygranum, even when the same serum reacted equally with normal yolk sac control material. We,

on the contrary, have emphasized from the outset the difficulty of reaching any valid decision as to the specificity of a Lygranum complement fixation test when there is equal degree of fixation with the normal yolk sac control. We have considered the combined reactions as nonspecific since they are in most instances due to yolk material not removed during the preparation of the viral antigen; it is known, for example, that yolk lipids enhance the sensitivity of serologic reactions used in the diagnosis of syphilis. Our own data have included as positive reactions only those where fixation with lymphogranuloma virus antigen was marked and the reaction with yolk sac control material was entirely lacking or minimal. More recently it has been shown^{17c} that many of the nonspecific reactions obtained with syphilitic sera can be eliminated through the use of antigen preparations treated with phenol and/or boiling.

Knott and co-workers²⁶ found that for syphilitic sera showing fixation with normal yolk sac material as well as with Lygranum antigen, absorption with Eagle flocculating antigen in many instances removed the reactivity versus both normal yolk sac control and viral antigens. A similar reduction in some cases followed antisyphilitic therapy; in other patients whose sera showed reactivity to both Lygranum and normal yolk sac control, antisyphilitic treatment was followed by a reduction in titer versus the control antigen while the titer versus Lygranum persisted. These results lend emphasis to our views as to the difficulty of assessing the specificity of fixation with Lygranum when the reaction with normal yolk sac material is also positive. Further, in certain syphilitic patients showing serologic reactivity versus Lygranum but not versus the control material, Knott and associates²⁶ observed that antisyphilitic treatment did not reduce the reactivity to Lygranum, nor did absorption with Eagle flocculating antigen remove the property from the serum. (See also^{11b, 23}.) They believed that in these latter cases at least part of the original reaction was due to specific antibody versus the virus, indicating lymphogranulomatous infection. They suggested that the results of Lygranum complement fixation in syphilitic patients could be evaluated best by repeated tests during the course of antisyphilitic treatment.

The Baltimore investigators were doubtful of the specificity of complement fixation with Lygranum because of the large number of positive tests they obtained with sera of patients giving no history or signs of overt lymphogranuloma. Koteen²⁷ has pointed out, however, that factual data are difficult to obtain from Negroes coming to a venereal disease clinic because these patients are prone to overlook small and painless lesions; negative histories therefore must be regarded with suspicion. Despite this, it may be noted that among thirty-four syphilitic patients of whom specific inquiry was made by Knott and colleagues, sixteen gave a history of previous genital lesions which might have been lymphogranulomatous.

Beeson and Miller²⁸ have recently made an important contribution to our understanding of the problem. They carried out Kahn and Lygranum complement fixation tests on 879 sera from an unselected group of white and Negro patients attending outpatient clinics at the Grady Hospital in Atlanta, Ga. The results were analyzed according to race, age, and sex. Among adult Negroes, the sera of approximately 40 per cent gave positive fixation with Lygranum and the sera of 32 per cent yielded positive Kahn tests. Among adult whites, the sera of 12 per cent gave positive fixation with Lygranum and 9 per cent gave positive Kahn tests. The age distribution of donors with positive serologic reactions followed much the same pattern for the Kahn test as for fixation with Lygranum, with a sharp rise in incidence after 14 years of age. The number of persons giving a positive test for one disease and a negative test for the other was in all groups greater than the number giving positive tests for both diseases. Furthermore, while 60 per cent of Negroes, both men and women, with positive Kahn gave positive Lygranum fixation, among the white patients with syphilis the sera of only 18 per cent of the men and 21 per cent of the women gave fixation with Lygranum, a racial difference which would not be expected if syphilis were a frequent cause of false positive serologic tests for lymphogranuloma. Beeson and Miller considered it probable that the high incidence of positive tests with Lygranum in individuals with syphilis and other venereal diseases is due to actual associated lymphogranuloma venereum infection, even in the absence of clinical findings.

From the data and discussion just presented, it appears that patients with evidence of another venereally acquired genitoinfectious disease (whether this be syphilis, chaneroid, or gonorrhea) frequently show positive cutaneous and/or serologic reactivity versus Lygranum. This is in sharp contrast to the low incidence of reactions observed in patients who have acquired the same diseases by nonvenereal means. We do not believe that the high incidence of serologic reactions in persons with diseases of such diverse etiology is due to nonspecific factors but rather attribute the great bulk of the reactions to an antecedent or concomitant infection with lymphogranuloma virus even though overt clinical manifestations of the latter may be few or lacking unless very careful search is made. A small proportion of the serologic reactions observed among these patients may, however, reflect a previous infection with some other member of the psittacosis-lymphogranuloma group.

6. *Tests on Sera From Persons With Miscellaneous Respiratory and Non-respiratory Infections.*—The data presented in the preceding sections have shown that complement fixation with Lygranum was exhibited by a high percentage of sera from (1) persons infected with agents of the lymphogranuloma-psittacosis group and (2) those with various infections of venereal origin. It seemed desirable to examine the sera of persons suffering from infections with agents unrelated to lymphogranuloma virus in which the likelihood of venereal acquisition was slight in order to determine the incidence of positive reactions in a contrasting group.

Among sixteen patients with clinically active tuberculosis, chiefly pulmonary, the sera of only two were positive versus Lygranum. One of the positive specimens was from a patient with a history of several previous attacks of gonorrhea; nothing was known about the venereal history of the second patient. The remaining donors, whose sera yielded negative results, included two with tuberculous lesions of the perianal region and genitals, respectively.

Among nine sera from patients with one of a variety of nontuberculous respiratory infections, none gave fixation with Lygranum. Similarly, in the group of eight patients listed as having various nonrespiratory infections, the complement fixation tests with Lygranum were uniformly negative (Table VI).

It is evident from the foregoing that neither the mere presence of an acute or chronic infectious process nor its localization in a site frequently affected by members of the psittacosis-lymphogranuloma group of viruses can be responsible for the findings reported in Sections 1, 3, 4, and 5 of this paper. Our failure to obtain complement fixation with lymphogranuloma antigen among the sera from the group of patients with assorted respiratory infections (Table VI), including atypical pneumonia of origin unrelated to the psittacosis-lymphogranuloma group (see Section 3), is in contrast to the findings of Florman²⁵ and Dulaney and Paeker²³ who did obtain reactions with Lygranum C. F. in tests on sera from patients with various respiratory infections. It is possible that the difference in results may be due to the fact that we employed antigens in which the virus was separated from the bulk of host tissue materials, whereas the commercially available Lygranum used by these workers was

less refined. As pointed out previously, Thomas and co-workers³⁵ have shown that the sera of patients with atypical pneumonia have a tendency to fix complement in the presence of relatively crude suspensions of a variety of animal tissues.

*Titers reported < signify that the specimens were anticomplementary at lower dilutions tested and negative at the titer indicated.

7. *Tests on Sera From Persons With Certain Organic Diseases.*—For additional information as to the range of specificity of the complement fixation obtained with Lygranum, tests were made on the sera of patients with evidence of neoplasia or cardiovascular, renal, or hepatic damage.

In the group of fourteen patients with neoplasia, the following manifestations were included: carcinoma of stomach, 2; carcinoma of sigmoid colon, 1; carcinoma of rectum, 2; papilloma of rectum, 1; rectal polyp, 2; carcinoma of pancreas, 2; carcinoma of gall bladder, 1; carcinoma of prostate, 1; lymphoma, 1; lymphosarcoma, 1. On examination one serum was anticomplementary to high titer; two other sera were anticomplementary at initial dilutions of 1:15 and 1:5, respectively, but at higher dilutions gave no evidence of specific fixation. The only positive reactions (titers 15 and 6) were obtained with sera from two men who exhibited rectal carcinoma and rectal polyp, respectively.

The fifteen patients with evidence of cardiovascular damage included individuals with congenital heart disease, various degrees of arteriosclerosis, hypertension, rheumatic heart disease, or subacute bacterial endocarditis. Only one serum, taken from a patient with rheumatic heart disease who also had a history of thyroidectomy, diabetes, and postoperative tetanus, was positive and this solely at the lowest dilution tested (titer 6).

Among ten patients with evidence of kidney damage, including glomerulonephritis, pyelonephritis, nephrosis, horseshoe kidney, pyelitis, staghorn calculus, or sulf- and methemoglobinuria, none of the sera showed specific fixation with Lygranum.

On the other hand, in a group of twenty patients with liver damage, in most of whom a diagnosis of cirrhosis was made, the sera of eight individuals gave definite fixation with titers ranging from 6 to 60 (Table VII).

Discussion: The examination of sera from persons with cardiovascular or renal disease or neoplasia offered little or no evidence that complement-fixing antibodies versus Lygranum are developed as a result of any of these conditions per se. The positive reactions obtained with an appreciable proportion of sera from individuals showing signs of liver damage and with no overt evidence of lymphogranulomatous infection were at first rather surprising. The nature of these reactions is still not clear, and we are not in a position to draw any definite conclusion as to the antecedent history of the patients which might be responsible for this behavior of the sera. It is well known that increased globulin and decreased albumin levels may be encountered in hepatic cirrhosis, so it might be assumed that the complement-fixing reactivity of the sera with Lygranum is due to physiologic changes which are of an immunologically non-specific character. There is also the possibility that some of the positive complement fixation reactions in this group of patients may indicate infection with some, perhaps as yet unrecognized, virus related antigenically to the members of the psittacosis-lymphogranuloma group of agents which may result in liver damage simulating that of cirrhosis.

Certain recent observations³⁹ are of interest in this connection. It has been possible to show that when mice are inoculated intravenously with a sufficiently large dose of the agent of mouse pneumonitis (Nigg), most of the animals will die within three or four hours. With smaller doses, however, life may be prolonged for as long as a week or more. Many of these mice become bloated and at autopsy show generalized edema, ascites, and pleural effusion as well as microscopic changes of early cirrhosis in the liver. Other observations given in the afore-mentioned studies³⁹ and elsewhere⁴⁰ have shown that all of the toxins of the psittacosis-lymphogranuloma group of agents cause damage to the liver cells in particular. This would support the view that some cases of human cirrhosis may be due, in part at least, to infection with an agent belonging to this group. (See also ^{41, 42}) Since most instances of cirrhosis, however, are undoubtedly due to other causes, the negative serologic findings with the majority of cirrhotic sera are readily explained.

8. *Tests on Sera From Laboratory Personnel.*—As part of our control series we have tested the sera of thirty-two laboratory workers, chiefly from New Brunswick personnel; the results are summarized in Table VIII.

TABLE VIII. LYGRANUM COMPLEMENT FIXATION TESTS ON SERA OF LABORATORY PERSONNEL

HISTORY OF LYMPHOGRANULOMA VENEREUM	NUMBER OF PERSONS TESTED	COMPLEMENT FIXATION			FREI REACTION POS.
		POS.	NEG.	NONSP.	
Negative	28	0	27	1	—
Equivocal	1	1	0	0	1
Laboratory infection	5	5*	0	0	5

*The sera of two of these workers, taken before the known infection, had been negative.

Sera from five cases of undoubted laboratory infection were examined. One was from a worker in another laboratory who developed lymphogranulomatous ophthalmitis⁴³; his serum gave definite fixation with Lygranum antigen to a titer of 60. Two New Brunswick workers contracted the disease during the course of intensive animal experimentation with highly infectious material.¹⁹ In each, the complement fixation titer of the serum rose markedly and subsided only very gradually despite the rapid alleviation of clinical signs and symptoms as a result of sulfathiazole therapy. The strongly positive Frei reactions which both workers showed in the early stages of their illness diminished in intensity during the year subsequent to infection, as shown by repeated tests during this period. Still another member of the New Brunswick personnel who was exposed to very infectious material during the frequent handling of glassware containing lymphogranuloma virus developed fever, general malaise, and pain in the region of the left shoulder due presumably to local adenopathy. In this case also, the Frei and complement fixation tests were strongly positive (serum titer 480) and administration of sulfathiazole resulted in the clearing of the general and local malaise. In the fifth individual the presence of lymphogranuloma was undiagnosed until routine complement fixation tests on the laboratory personnel revealed that his serum was strongly positive versus Lygranum. He had assisted in the care of lymphogranulomatous mice for several months and was discovered to have a history compatible with that of recent accidental infection including the development of minor herpetiform lesions on the back of one hand together with general malaise, slight fever, and headache over a

period of several weeks. His condition showed marked amelioration following treatment with sulfathiazole per os.

Discussion: From the foregoing observations of laboratory workers we conclude that the sera of persons in whom the likelihood of infection with agents of the lymphogranuloma-psittacosis group is minimal rarely contain complement-fixing antibodies versus Lygranum antigen. Knott and co-workers³⁵ obtained similar results on testing twenty white members of the hospital staff personnel as controls in their study; all of these gave negative reactions to the cutaneous and serologic tests with Lygranum.

On the other hand, cases of laboratory infection with lymphogranuloma virus, even though acquired by routes and modes other than those usual for this disease, not only become Frei positive, but also develop complement-fixing antibodies early in the course of illness, sometimes within a week after the onset; these may persist in the serum for over two years, although with the cessation of clinical activity and the possible elimination of the incitant as a result of intensive therapy with drugs of the sulfonamide group, the antibody titer tends to diminish and the Frei reaction may become completely negative again. In patients with early manifestations of the naturally acquired disease, similar reversal of the Frei reaction as a result of vigorous sulfonamide chemotherapy has been reported by others,^{36, 37, 44} although it does not commonly occur.

It may be pointed out that, as in the natural disease, laboratory infections with the virus of lymphogranuloma may vary widely in clinical manifestations. Some are mild⁴⁵ and would be unnoticed unless a Frei or complement fixation test were performed, while others may present signs of acute systemic disease.¹⁹ It would seem a highly desirable precaution that individuals working intensively with the agent should perform complement fixation tests on their own sera at frequent intervals to check on the possibility of infection.

9. Tests on Sera From Persons With Genitoingual or Lower Bowel Lesions of Questionable Origin.—In the course of this study there was opportunity to investigate the value of the complement fixation test in affording evidence to confirm or exclude the diagnosis of probable infection with the agent of lymphogranuloma venereum in: (1) patients with genitoingual lesions compatible with those of early lymphogranuloma but in whom the Frei test was not definitely positive; (2) patients with genitoingual lesions of questionable origin but with positive Frei reaction; (3) patients with genitoingual lesions of questionable origin and negative Frei reaction. From Table IX it may be seen that in the small number of cases tested, complement fixation with Lygranum was regularly obtained with the sera of patients in the first two groups but with only certain sera from patients in the third group. In this latter group the positive results were obtained in those patients whose history and signs suggested the possibility of previous lymphogranulomatous infection.

In Table X are summarized the data on seventeen patients, each of whom presented one of a variety of lower bowel lesions of questionable origin. Two patients showed positive or doubtful Frei reactions, and the sera of both gave fixation with Lygranum. Among the remaining fifteen patients, the sera of only four yielded positive reactions. As might be expected, this incidence is con-

siderably lower than was observed with the sera of persons who showed bowel lesions regarded clinically as lymphogranulomatous and who also yielded positive Frei reactions (see Table I).

Discussion: The limited data presented in this section indicate that the complement fixation test with *Lygranum* may be of definite aid in the establishment of an etiologic diagnosis in certain cases of genitoinguinal or lower bowel disease where the lack of a positive Frei reaction or the character of the lesions raises some doubt as to their lymphogranulomatous nature. In such cases repeatedly negative serologic tests would make infection with the agent of Nicolas-Favre disease seem highly unlikely, while positive tests are suggestive of an infection with some member of the lymphogranuloma-psittacosis group of agents and call for further study of the patient, including repeated Frei tests. It has been observed that the latter may subsequently become positive, thus confirming the earlier serologic findings.

patients with urogenital lesions of questionable origin. Of eleven persons with urethral disease but with no evidence of infection by other venereal agents, four who gave positive Frei reactions and one with a doubtful Frei reaction also showed serum antibodies reacting with Lygranum antigen. In these cases the observed clinical manifestations would appear to be due to lymphogranulomatous infection; instances of abacterial urethritis believed due to this cause are already recorded in the literature.⁴⁶ Five additional individuals in the group with urethral lesions (including one with a history of gonorrhea) exhibited complement-fixing antibodies although the Frei reaction was negative. Since it is known that some cases of urethritis may be due to the virus of inclusion conjunctivitis⁴⁷ and since the sera of two persons with ocular diseases due to this agent were previously noted to give fixation with Lygranum antigen,¹² it cannot be stated which of these two related viruses may have been responsible for the urethritides in the group with negative Frei reactions.

In twenty-three patients with bladder disturbances, on the other hand, only five showed complement-fixing antibodies versus Lygranum, and four of these also gave positive Frei reactions indicating that they had been infected with lymphogranuloma virus. A more detailed account of the clinical findings in these five patients has been presented by Marshall and Endicott.⁴⁸

COMMENT

It seems desirable to summarize here our present information regarding the immunologic features of human lymphogranulomatous infection since this knowledge is prerequisite to the proper interpretation of the data presented in the preceding sections.

Following the introduction of active lymphogranuloma virus in the body, there is usually a relatively prompt appearance of complement-fixing antibodies which may be detected as early as a week after the time of infection¹⁰; during the subsequent few weeks the titer rises to a maximum, the level of which will vary with the individual. Increase in the serum globulin may also appear prior to the acquisition of cutaneous reactivity⁴⁹ which usually, though not invariably, develops after an interval of several weeks of infection.^{12, 50, 51} The clinical activity of the individual case would appear to play some, but not necessarily the major, role in determining the intensity of the cutaneous reaction as well as the serologic titer.

In the person who does not receive effective therapy the disease may regress spontaneously or may continue active for long periods of time. Even when the disease becomes clinically healed living virus may continue to reside in the tissues, perhaps dormant but still capable of stimulating the continued production of complement-fixing antibodies and enduring reactivity to the Frei test. Thus patients whose lymphogranulomatous infections date back many years will often give positive cutaneous reactions to Frei or Lygranum antigens^{3, 6} as well as complement fixation with the latter⁵²; they may still be infectious for their sexual partners and, moreover, active virus has in some instances been recovered experimentally from these cases of long duration.³ The prolonged stimulation by viral antigen frequently results in the marked synthesis of complement-fix-

ing antibody, this being reflected in a high serum titer and probably also in the extent of the hyperglobulinemia so frequently noted in this disease.^{12, 19, 53}

If a patient with early signs of the disease is given vigorous and adequately prolonged treatment with an effective drug such as one of the sulfonamides, the infection may be sterilized. In such case the skin hypersensitivity will wane, and over a period of months one may observe an actual reversal of the Frei reaction^{9d, 19, 37, 41}; the level of complement-fixing antibodies also falls gradually, but reactions of low titer may still be demonstrable for many months after the skin reactivity has disappeared.¹⁹ There is evidence that with clinical improvement the elevated serum globulin level may also decline toward the normal.^{29, 53d, 53e}

It is well known that there may be considerable variation among individuals in their response to a given antigenic stimulus whether this is encountered in the course of clinical disease or during artificial immunization. Undoubtedly similar variation is shown in the reaction to lymphogranuloma virus, which in most patients appears to constitute a fairly potent antigenic complex. It should not be expected, therefore, that every individual who is infected with the agent will show definite cutaneous reactivity or antibody production, although the vast majority do, in fact, exhibit these responses.⁵¹

Are these two responses manifestations of a single immunologic mechanism or are they the result of different antigenic stimuli? It is true that some general correlation has been noted between the serum titer and the dimensions of the cutaneous reaction in lymphogranuloma²²; this may be considered as favoring the first possibility, namely, that the positive Frei reaction depends on the presence of an adequate quantity of complement-fixing antibody in the circulation. The correlation is by no means invariable, however, and there is other evidence which would appear to favor the alternative hypothesis. In the first place, most cutaneous reactions due to the local union of antigen with circulating antibody are of the immediate variety, whereas delayed reactions are seen in the so-called bacterial allergies, wherein passive transfer with antiserum cannot be demonstrated. The Frei reaction is a delayed reaction resembling the reaction to tuberculin or chaneroidal antigen. In the second place, infants born to lymphogranulomatous mothers rarely give positive Frei reactions⁵⁵ although passive transfer of complement-fixing antibodies across the placenta occurs regularly.^{38, 56} Further, persons infected with other viruses of the psittacosis-lymphogranuloma group may develop potent complement-fixing antibodies which will react with Lygranum, yet fail to give positive cutaneous reactions with this antigen.^{12, 57} Finally, we have obtained certain limited evidence (vide infra) which suggests that the complement-fixing antibodies may be evoked by inactive virus while the stimulus of living lymphogranuloma virus within the body is a prerequisite for the development of cutaneous reactivity.

Eight normal laboratory workers received, over a period of several months, repeated (up to ten) intradermal and subcutaneous injections of 0.25 to 1.0 ml. of formalinized Lygranum antigen, quantities many times greater than those which would be used in a cutaneous test. Their sera were tested from time to time and in two members of the group no antibodies were found; one person developed a titer of 6; three persons showed a titer of 15; two workers developed a titer of 60. None of the eight showed a positive cutaneous reaction to Lygranum, although lymphogranulomatous patients with a serum titer as low as 6 usually give a positive intradermal reaction, frequently of marked intensity. One of the workers with serum titer of 60 subsequently acquired active infection in the laboratory, following which the skin reaction became strongly positive; the serum titer also showed a further rise. The failure of Lygranum to induce cutaneous hypersensitivity in nonlymphogranulomatous individuals despite repeated injections is in agreement with the behavior of human Frei antigen under similar circumstances.^{50, 51, 58}

With the foregoing in mind, we are now in a better position to consider Lygranum complement fixation in the diagnostic study of patients concerning whom the question of lymphogranulomatous infection is raised. We believe the following statements to be justified on the basis of the available data.

Among individuals with authentic lymphogranulomatous disease, irrespective of localization, nearly all will yield positive complement fixation as well as cutaneous tests with Lygranum. Only very rarely will a positive Frei reaction be obtained in the absence of serologic reactivity (see Section 1). By and large the complement fixation test, as we have performed it, appears to be definitely more sensitive and it will therefore detect an appreciable proportion of reactors who fail to yield definitely positive cutaneous tests (see Section 9). The serologic test may become positive before skin hypersensitivity has developed and may persist after the waning of the latter (see Section 8).

There are numerous patients who are asymptomatic but who exhibit definite reactivity to cutaneous and serologic tests with Lygranum. In such persons the demonstration of positive responses in both tests is strong evidence in favor of antecedent infection with the virus of lymphogranuloma, whether or not there are overt signs of Nicolas-Favre disease. Instances of this sort are not infrequently encountered among those who have acquired other venereal disease (see Sections 4 and 5) as well as among marital partners of persons who themselves present evidence of pre-existing lymphogranuloma.

In patients who show complement-fixing antibodies versus Lygranum but who do not react to cutaneous tests, the decision as to diagnostic significance requires consideration of the following possibilities. Some of these serologic reactions may reflect lymphogranulomatous infection in persons with skin anergy^{50, 51, 54, 59}; it has been noted in this connection that a temporary reduction in cutaneous reactivity to Frei antigen may sometimes occur during an early syphilitic infection.^{54b, 60} In certain cases cutaneous reactivity may not yet have developed or a previously existing reactivity may have faded due to sterilization of the infection while antibodies have persisted as testimony to the former presence of virus (see Section 8). In other instances, the reactions may be due to infection with a related virus such as those of ornithosis, inclusion blennorrhoea, or trachoma (see Section 3). In this group of patients, therefore, the results of a single complement fixation test do not allow a dogmatic conclusion about the nature of the antecedent infection in any individual case; repeated quantitative serologic tests to determine possible alterations in titer with the passage of time, as well as a carefully taken history, may throw additional light on the etiologic background.

It was formerly believed that Nicolas-Favre disease was relatively uncommon and that it nearly always manifested itself in a frank syndrome. During the past fifteen years our knowledge of the nature and extent of the infection has been altered radically. This is due in part to the demonstration of an unexpectedly large number of clinical cases in communities where the prevalence of the disease had not been appreciated previously^{16, 61} and to the discovery of a high incidence of positive Frei reactors among those groups in the population

where promiscuity, and poor sexual hygiene frequently eventuate in other venereal infections.^{1d, 41} The results of complement fixation tests with Lygranum have extended the data previously obtained from cutaneous tests. There is now abundant evidence that the natural history of lymphogranulomatous infection is in some respects not unlike that of tuberculosis or syphilis. All are highly contagious, but in many individuals the infections are so mild that they pass unnoticed unless thorough physical examination and history are obtained; other persons experience subclinical or asymptomatic infections which are only detected by immunologic methods. With the limitations previously noted, the complement fixation test with Lygranum is a valuable epidemiologic tool, since it can serve as a screening device for the selection of those elements in the population which might most profitably be further investigated.

SUMMARY

1. In a group of 149 patients who showed a wide variety of overt lesions regarded clinically as lymphogranulomatous and who gave positive cutaneous reactions to lymphogranuloma antigens, the sera of over 98 per cent were found to fix complement in the presence of Lygranum.

2. The antibody titers varied markedly among individuals; differences as great as several hundredfold were observed. It was noted that with the technique employed approximately 10 per cent of the lymphogranulomatous sera reacted, but weakly, giving definitely positive results only in the lowest serum dilution tested (titer 6 by our notation).

3. The limited data available suggested a correlation between the titers of complement-fixing antibodies and the globulin values of lymphogranulomatous sera.

4. Complement-fixing antibodies versus Lygranum were also demonstrated regularly in the sera in several cases of accidental laboratory infection with the virus and in the sera of groups of Frei-positive persons (1) who showed evidence of urogenital localization of lymphogranuloma, or (2) who showed lesions of questionably lymphogranulomatous origin, or (3) who appeared asymptomatic in regard to lymphogranuloma venereum.

5. In healthy individuals (for example, laboratory workers) who were not known to have had contact with viruses of the lymphogranuloma-psittacosis group, the complement fixation test with Lygranum gave negative results. In contrast, the sera of patients who were known to have been infected with other members of this group of related viruses in most instances gave reactions with lymphogranuloma antigens.

6. Reactions were only rarely observed among patients suffering from non-venereal infectious diseases due to agents unrelated to the lymphogranuloma-psittacosis group, irrespective of the site of localization.

7. The sera of patients with neoplasia or cardiovascular or renal disease seldom showed reactions with Lygranum. An appreciable proportion of the sera from a group of patients with evidence of hepatic damage did show such complement fixation; the possible significance of this is discussed.

8. The results of complement fixation tests with Lygranum supported the concept that among those who acquire other genitoinfectious diseases as a consequence of sexual promiscuity there may frequently occur a concomitant infection with the virus of lymphogranuloma venereum.

9. The analysis of the available data indicates that the complement fixation test with Lygranum has certain limitations but may properly be considered useful in diagnostic and epidemiologic studies.

We wish to record our particular thanks to Dr. A. W. Grace and Dr. M. E. Howard, who furnished us with many of the sera used in this study as well as much valuable information concerning the donors. We are also grateful to the following colleagues who kindly furnished additional sera and the pertinent clinical data: Dr. T. Badger, Dr. T. M. Brown, Dr. H. B. Curth, Dr. W. B. Dunham, Dr. J. H. Dingle, Dr. M. D. Eaton, Dr. M. Finland, Dr. G. Hobby, Dr. C. A. Janeway, Dr. F. E. Kendall, Dr. B. A. Kornblith, Dr. H. Lee, Dr. T. P. Magill, Dr. V. F. Marshall, Dr. K. F. Meyer, Dr. G. Morris, Dr. J. V. Mulachy, Dr. J. F. Mahoney, Dr. J. W. Oliphant, Dr. H. Pearson, Dr. M. G. Perez, Dr. H. Robinson, Dr. A. B. Sabin, Dr. H. C. de Souza Araujo, Dr. P. Thygeson, and Dr. B. Webster.

We deeply appreciate the cooperation of our associates of the Squibb Institute for Medical Research and the Biological Laboratories of E. R. Squibb & Sons, who furnished sera and who volunteered to receive repeated injections with Lygranum.

COAGULATION TIME OF BLOOD HEPARINIZED IN VITRO: CORRELATION OF RESULTS WITH THOSE OF THE HEPARIN TOLERANCE TEST

ALBERT B. HAGEDORN, M.D., AND NELSON W. BARKER, M.D.
ROCHESTER, MINN.

RECENTLY we reported on a heparin tolerance test¹ and gave results obtained in a study of normal subjects and patients suffering from various types of intravascular thrombosis. This paper is presented to show the results obtained with a test of coagulation time of whole blood heparinized in vitro and to compare these results with those obtained with the more complex heparin tolerance test.

The idea of determining coagulation time after adding heparin to blood in vitro rather than in vivo was suggested by papers published by Waugh and Ruddick.^{2, 3} These workers used a series of test tubes containing progressively increasing amounts of heparin, each of which contained 1 ml. of venous blood. After the coagulation time of the blood in each of the tubes was determined, a curve was charted and from this they derived their conclusions. We wished to establish a simpler procedure.

If the blood volume of an average normal adult were 5 liters, 25 mg. of heparin given intravenously for a heparin tolerance test would produce a concentration of 0.005 mg. of heparin per cubic centimeter of blood ten minutes after injection, at which time the blood and heparin should be mixed completely. Arbitrarily then, we decided to determine the coagulation times of 1 ml. of blood drawn from normal persons and patients suffering from intravascular thrombosis when the blood was added immediately after withdrawal to 0.005 mg. of heparin. Obviously, after an intravenous injection of 25 mg. of heparin the concentration of heparin is not always 0.005 mg. per milliliter of blood, since the blood volume of adult individuals varies. Hence, a slight discrepancy might be expected in comparing the coagulation times of blood obtained in the heparin tolerance test and in the test of heparinized blood in vitro.

The coagulation test of blood heparinized in vitro was performed as follows. Three 10 by 75 mm. glass tubes were used for each test. One tube was left empty. In the second tube, 0.5 ml. of a 0.9 per cent solution of sodium chloride without heparin was placed. In the third tube, 0.005 mg. of heparin dissolved in 0.5 ml. of 0.9 per cent solution of sodium chloride was placed. Blood was withdrawn from the antecubital vein and 1 ml. was measured carefully and placed in each of the three tubes. The second and third tubes were vigorously inverted three times as soon as the blood was added in order to mix the blood

From the Division of Medicine, Mayo Clinic.

Abridgment of thesis submitted by Dr. Hagedorn to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Medicine.

Received for publication, May 27, 1947.

with the solutions. The timing was begun as soon as the blood was drawn from the vein into the syringe. All tubes were inverted at thirty-second intervals until clotting occurred as in the heparin tolerance test. All tests were carried out at hospital room temperatures. Inasmuch as some question arose concerning loss of potency of the dilute solution of heparin used in the test, a fresh solution of the heparin (10 mg. in 1,000 ml. of 0.9 per cent solution of sodium chloride) was made every seven days or oftener as needed.

The coagulation time of blood heparinized (0.005 mg. per milliliter) in vitro was determined, and the heparin tolerance test was carried out successively on the same day in forty-five persons. The results of the two tests are compared in Tables I and II.

The coagulation time of 1 ml. of blood did not differ significantly from that of 1 ml. of blood mixed with 0.5 ml. of 0.9 per cent solution of sodium chloride (Tables I and III).

In this study the coagulation times of blood heparinized in vitro and in vivo were essentially similar for each of the persons who were tested. Relatively slight differences may be explained by variations in blood volumes from 5,000 ml. in different individuals and also are probably within the limits of the experimental error inherent in either method.

The results of the heparin tolerance test can be closely duplicated by testing the coagulation time of blood added to heparin in vitro immediately after withdrawal if the concentration of heparin is approximately the same. The coagulation time of heparinized blood in vitro is a simpler test.

A NEW METHOD FOR THE INDIRECT MEASUREMENT OF BLOOD PRESSURE IN THE RAT

H. KERSTEN,* W. G. BROSENE, JR., F. ABLONDI, AND Y. SUBBAROW
PEARL RIVER, N. Y.

VARIOUS methods for the indirect measurement of blood pressure of the rat have been reported in the literature¹⁻³ and summarized in *The Rat in Laboratory Investigation*.† It has become common practice to determine the blood pressure of the rat by the method of Williams, Harrison, and Grollman.² The divergent and inconsistent results obtained by comparison of both direct and indirect blood pressure measurements led Schroeder⁴ to doubt the validity of the various indirect methods of measurement of blood pressure in the rat. Shuler, Kupperman, and Hamilton⁵ attributed these discrepancies to the size of the sphygmometer cuff applied to the base of the tail and to the sensitivity of the plethysmograph. By changing the membrane of the plethysmograph to a much finer membrane, and by making the size of the oncometer tube attached to the plethysmograph much smaller ($\frac{1}{2}$ mm.), they were able to increase the sensitivity of the instrument. However, these workers did not give any blood pressure values for unheated, unanesthetized normal animals obtained with these changes, although many values were reported for the anesthetized normal animal. Proskauer, Neumann, and Graef⁶ studied independently the problem of these discrepancies. Using the apparatus of Williams and co-workers,² modified so as to be in agreement with the changes recommended by Shuler and associates,⁵ they came to the following conclusions. "The systolic pressure of trained, normal unanaesthetized rats, as measured by a modification of the indirect method in which there was no change in the rectal or cutaneous temperature, was 65 to 95 mm. Hg at room temp. 24-28° C." These blood pressure values were still inconsistent with those of direct puncture, although Shuler and co-workers got higher values by the indirect method which agreed with the direct method when the rats were anesthetized.

Since we had been aware since 1943 of the discrepancy between the direct and indirect methods of blood pressure measurement, we also independently sought methods by which these disagreements could be explained. On the assumption that the tail method of Williams and co-workers was fundamentally sound, we attributed our inability to use the method to the relative inability of the described apparatus to measure the small volume changes taking place in the tail before and after constriction of the sphygmometer cuff. To overcome this obstacle, we resorted to a very sensitive photoelectric system by which the change in volume of the tail was measured by the change in the size of a slit formed between a metal knife-edge adjusted to form the slit by nearly touching the upper surface of the tail. The distance of the upper surface of the tail from

the metal knife-edge depends on the total volume of the tail which changed on lowering or raising the pressure in a sphygmometer cuff above or below the systolic pressure. Even with this extremely sensitive system the necessity of heating normal unanesthetized animals in order to obtain volume changes in the tail was not completely overcome. The results obtained⁷ were very much in agreement with those of Proskauer and co-workers. During the course of our experiments, it was observed that:

1. Even with our more sensitive method of recording volume changes in the tail, we were generally unable to obtain volume changes without heating the animal.

2. As the rats were warmed, readings could gradually be obtained, the volume change being greater as more heat was applied. However, these volume changes did not occur at the same sphygmometer pressure-cuff pressure but at higher indicated pressures. There seemed to be a proportionality between temperature and observed blood pressure reading.

3. When the rats were heated excessively the blood pressure reading fell suddenly to very low levels.

4. In attempting to standardize the rate of heating, different rats responded differently to the same heating conditions, and the same rat responded differently on different days to given heating conditions.

5. There were no optimal conditions under which comparable blood pressures were obtained in the same rat or in different normal rats.

6. Rats which gave no indirect readings at normal room temperature, when umbilicalized, gave indirect blood pressure readings at normal room temperature and higher readings when heated under anesthesia.

For these reasons, it was obvious that a more dependable method of indirect blood pressure measurement would have to be developed if the rat were to be used for chronic blood pressure studies. This method would have to fill the following prerequisites:

- (1) The indirect method of determining the blood pressure must be on some appendage other than the tail, in order to obviate the "reflex vasoconstriction" of the arteries of the tail which was influenced by heating or anesthetizing the animal.

- (2) The normal, unheated, unanesthetized animal must be used in order to eliminate all contributing factors which would influence blood pressure.

- (3) In taking the blood pressure, control of all physical factors (light, handling, type of restraint, etc.) which would affect blood pressure must be possible.

After approximately one and one-half years of further study an instrument and a technique was developed which met the stated requirements. It depends on (1) use of the foot (Griffith's technique),¹ and (2) measurement of volume change (Byrom and Wilson,² and Williams and associates³) of the foot (Griffith) by means of the change in volume and intensity of light as measured by a photocell-microammeter arrangement.

The instrument and technique which have eventually given us the mentioned prerequisites are described below.

The Rat Holder.—The restraining cage has been developed with a view to comfort and darkness (for quietness); it is well ventilated and so constructed as to leave the two hind legs suspended freely at the groin. The "head" part of the cage is of metal with a large overlapping cover. This cover is not airtight and permits free entrance of air but not light. At approximately the chest region of the rat a leather "body holder" is fixed to the metal head case with a clamp. This leather is split along the "back." At the "tail end" of the cage two holes are made through the leather to permit the legs to hang. When the rat is in the cage the split on the "back" of the cage is held closed by means of clips. When the rat has been in the cage for a minute or so, it usually relaxes and remains quite still (see Fig. 1).

Fig. 1.—Photograph of rat holder and various types of rat foot holders.

The Sphygmometer Cuff.—The type of sphygmometer cuff necessary required standardization in making them. A study has been made of different cuffs varying in cross-sectional thickness of the wall and in cross-sectional diameter of the tube itself.

The cuffs are made as follows:

Natural Latex* is well emulsified and filtered through cheesecloth into a graduate. It is allowed to stand for one hour, after which time any minute air bubbles in the top of the emulsion are brushed off with scraps of filter paper.

Glass rods of the desired diameter, approximately ten to twelve inches long, are cleaned well, rinsed with distilled water, and then rinsed with 3 per cent ammonia water. They are allowed to air-dry and then are dipped into the latex. The rods are carefully (without touching the sides of the graduate) with-

*Obtained from General Latex and Chemical Co., Cambridge, Mass.

drawn at a constant rate of speed. (A geared electric motor with a spindle is very desirable.) The rate of withdrawal of the rod determines the wall uniformity and thickness of the rubber tube. Usually four inches a minute has been the satisfactory speed. A single dipping will give a thin rubber tube which does not stand excessive use. After permitting the rod to air-dry for 1.5 to 2 minutes, the rod is again immersed and withdrawn at the same speed. It is allowed to air-dry as before. Any minute air bubbles may be removed from the rod by blowing gently on the rod or by carefully touching the air bubbles with the torn edge of a piece of filter paper. The rod may be dipped as frequently as desired for building up the wall thickness.

Fig. 2 —Preparation of sphygmometer cuffs.

The rod is then allowed to air-dry for seventy-two to ninety-six hours, or the process may be speeded up by heating in an oven at 99 to 100° C. for four to six hours. When dry, the rubber tubing is removed from the rod by lubricating thoroughly with a glycerine (3 Gm.)-talc (1 Gm.) mixture both externally and internally as it is freed from the rod. When completely free of the rod, the rubber tube is washed with water, dried, and lubricated with talc. Sections of desired length may be cut as needed.

The size cuff most practical and efficient has been found to be a 2-dip, five-inch per minute 5 mm. diameter tube. A length of approximately 7 cm. is cut off and sealed at one end with rubber cement. The other end is joined and cemented to 8 to 12 cm. of 5 mm. catheter tube. A 9 cm. piece of one-fourth or five-sixteenth inch ribbon is also cemented to the catheter by winding with a 5 mm. wide strip of latex cut from a sheet (see Fig. 2).

Cuffs of varying outside diameters and wall thicknesses have been prepared, and corresponding variations in the indicated blood pressure were determined. When cuffs less than 4 mm. diameter (when flattened out) are made by a 2- or more, dip procedure, the wall thickness begins to play a role and excessively high recorded pressures ensue since the resistance of the rubber must be overcome in order to compress off the circulation into the foot. An initial standardization of cuffs, making a comparison with a direct puncture, would be advisable for one who has not had previous experience to be sure that the cuffs are of the proper thickness.

Fig. 3.—Illustration of positions of foot, foot holder, cuff, light, and position of rat for taking the blood pressure.

The Photocell-Microammeter Volume Change Indicator.—As shown in Fig. 3, the only light striking the photocell is that which passes through the foot from the light source. This value of light will remain constant as long as the foot is still and allowed to function normally. But when the flow of blood leaving the foot is restricted, the foot will begin to swell, causing a decrease in the amount of light striking the photocell. The circuit for the indicator is shown in Fig. 4. High impedance pentode tube acts as a load impedance for the high

impedance vacuum type photocell. The characteristic curves (Fig. 5) show that the potential of the common connection between the phototube and the pentode is determined by the intersection of their characteristics. It is also evident that a very small change of light on the photocell will result in a correspondingly large voltage change. This output voltage is applied to the grid

Fig. 4.—Circuit of the photocell microammeter volume change indicator.

Fig. 5.

of the 1S4 output tube, the plate current of which is indicated on the 0 to 200 microammeter.⁸

The Foot Holder.—It must be pointed out that the footholder was designed not to hold the foot in position forcibly, but only to restrain if the rat attempts to withdraw the foot, so that the foot does not leave its correct position. This foot holder is not absolutely necessary but has been an aid in training the rats, and once trained they are conditioned to its feel. A hole directly under the place where the "palm" of the rat's foot rests is also made. This leads directly over the photocell. (See Figs. 1 and 3.)

Sensitivity.—By sensitivity is meant the responsiveness of the instrument to a given change in amount of light hitting the photocell. This is taken care of by the circuit itself.

Accuracy.—By accuracy is meant the amount of lag between the first change in volume in the foot caused by lowering the pressure of the sphygmometer cuff and the recording of the change in volume on the galvanometer. This accuracy is controlled by the intensity of the light source, the width of the cuff, and the size of the aperture, and also by the rate of lowering the sphygmometer cuff pressure. The intensity of light should be 10 to 35 foot-candles, when a Weston meter is held one inch from the source of light. The light should be directly over the aperture between one-half and one inch from the foot, so that the rays of light are perpendicular to the foot. The aperture in the foot holder which permits light through to the photocell can be from one-eighth to one-half inch in diameter. Interchangeable foot holders with holes of varying diameters have been used advantageously. The size of the cuff has been discussed.

Source of Light.—The light on the foot should be of a "heatless" type or transferred over the foot by a Lucite rod to eliminate heating the foot. A small 3.0 volt "lens type" "penlight" bulb has also been found convenient.

Taking the Pressure.—The rat is placed in the rat holder and allowed to remain for a minute or two with the two hind feet resting on the table or some other solid object. The cage should be clamped in a position so that the rat's body forms a 45- to 60-degree— \angle —angle with the table (Fig. 3).

The cuff is then wound around the area just above the ankle and held there by wrapping the ribbon around the cuff and clamping it to the catheter tubing with a "light pressure" clamp so as not to constrict the catheter tubing. This cuff should be kept well powdered with talc. The cuff should be applied rather loosely (but not too loosely) since the venous pressure must not be exceeded or circulation will be stopped and no change in volume of the foot will occur and, therefore, there will be no reading. If no reading is obtained, the cuff should be rewound.

The rat's foot is placed in position in the foot holder and the extinguished light is brought directly over the back of the foot which lies directly over the hole in the foot holder. The instrument is turned on, and the circuit resistance control is adjusted so that the microammeter shows that the photocell is being activated. The cuff (attached to the sphygmometer) is inflated to 250 mm., at which point the microammeter is adjusted to a reading of 150 microamperes by using a small rheostat on the light source. Small jumps or fluctuations on the

microammeter may be observed; these usually are due to movements of the foot of the rat (brought about by breathing, if the cage is not placed correctly, or by squirming) or to the interference of shadows falling on light-leaking parts of the photocell chamber. If less than ten foot-candles of light are used as the light source, shadows or reflections from the room lights onto the rat's foot will also cause erratic jumps of the microammeter needle. All extrinsic lights can be avoided by using a box over the instrument or by working in a darkened room.

The pressure is slowly lowered in the cuff at approximately 250 mm. to 0 mm. in 0.5 minute. When the systolic pressure is reached, a characteristic drop of the microammeter will be obtained. This drop will stop if the cuff is immediately inflated past the systolic pressure and will start again when the pressure in the cuff is again lowered. The microammeter will continue to approach zero

Fig. 6.—Assembled blood pressure instrument.

and may even speed up its dropping rate as pressure drops. The fall in microammeter reading is, of course, due to the change in volume of the foot incurred by blood flowing into the foot. This reduces the amount of light into the photocell.

When the pressure in the cuff gets below the venous pressure, the foot will recede to its original volume since blood can now leave the foot, and therefore the microammeter will rise to its higher reading. We have arbitrarily called this lower reading the "indicated" venous pressure, although its relationship to the actual venous pressure has not yet been established. The rate at which the cuff pressure is lowered, if too rapid, will give lower readings than if dropped more slowly, as is the case in any indirect blood pressure measurement. It has been our practice to get a range reading on the first trial by lowering the cuff

pressure at 250 mm. to 0 mm. in approximately 0.25 minute, followed by two or three readings at the standard rate of 0.5 minute for 250 millimeters. This, of course, is optional.

It has been observed that a waiting period of about one-fourth minute is necessary between readings. If no waiting period is taken, readings may not be obtained. See Fig. 6 for assembled blood pressure instrument.

EXPERIMENTAL

All rats received from Rockland Farms, Carworth, or our own breeding colony are placed in individual cages and numbered. In most cases no training of rats was necessary, but occasional rats were very difficult to control. As an example of the variation of normal blood pressure in these normal animals, obtained by use of the described procedures, the blood pressure of a group of seventeen rats was determined for three consecutive days. The rats varied in weight from 190 to 320 grams. The sphygmometer cuff used was 5 mm. wide and 8 cm. long, two-dip, five-inch a minute latex tubing.

The average mean determination in this first group of animals was 118 ± 12 mm. for the first day, 116 ± 9 mm. for the second day, and 117 ± 8 mm. for the third day. (It has also been possible to take the blood pressure of rats as small as 50 grams in weight, with the appropriate foot holder and rat holder.)

SUMMARY

A new method and instrument for the indirect determination of blood pressure of the rat has been described. This procedure does not require the heating or the anesthetization of the animal. The principle of its functioning is based on measuring the volume change in the foot by means of a photoelectric cell before and after application of pressure by means of a miniature sphygmometer cuff applied to the ankle of the foot.

By this method the average indicated systolic blood pressure of a group of seventeen normal, unheated, unanesthetized rats was found to be 117 mm. \pm 8 mm. Hg. The indicated venous pressure was found to be 18 mm. \pm 4 mm. Hg.

The authors are grateful to Miss L. Lipchuck, for assistance rendered in carrying out this work, and to Mr. L. McWilliams, for the photographs.

COMPARISON OF BLOOD PRESSURE MEASUREMENTS IN THE RAT AS OBTAINED BY USE OF THE TAIL AND FOOT METHODS AND BY DIRECT FEMORAL PUNCTURE

F. ABLONDI, Y. SUBBAROW, L. LIPCHUCK, AND G. PERSONEUS
PEARL RIVER, N. Y.

A NEW method for the indirect determination of the blood pressure of the rat has been described.¹ This procedure has obviated the necessity of prewarming or anesthetizing the animal, as compared with the previously described methods in the literature.²⁻⁷ It became of extreme interest to compare the blood pressures obtained by this method with the various methods under similar environmental conditions.

EXPERIMENTAL

The Tail Instrument.—All determinations of blood pressure made on the tail were carried out using the same type of photocell-microammeter system as described for the foot.¹ The change in volume of the tail was measured by the decrease or increase of light entering the photocell from a slit formed between the upper surface of the tail and a fixed metal shield before and after constriction of the tail with a sphygmometer cuff (Fig. 1). (In measuring the volume change of the foot, the amount of light going through the foot was measured before and after constriction of the ankle with a sphygmometer cuff.) This instrument gave sensitivities to volume changes on the order of, or greater than, the instrument of Williams and co-workers⁴ as modified by Shuler and associates⁵ or Proskauer and associates.⁶ Its sensitivity was also of the same order as the machine used on the foot throughout all the described experiments. The size of the cuff used on the tail was 9 mm. wide by 9 cm. long, dipped in the same manner as the sphygmometer cuff used on the foot and, therefore, of the same thickness of rubber. The cuff was wound around the base of the tail and held there by wrapping a ribbon 15 mm. wide around the cuff. The indirect blood pressure was taken in exactly the same manner as described for the Williams method except that the change in volume in the tail before and after constriction with the sphygmometer cuff was observed by the increase or decrease in light entering a photocell system rather than by a water plethysmograph.

The Foot Instrument.—The foot instrument has been described previously.¹

The Direct Puncture Manometer.—The instrument used for the direct measurement of blood pressure was a modification of Hamilton's optical manometer.⁸ Instead of using the diaphragm type of mechanism, our mirror was mounted on the end of a copper-beryllium Bourdon tube. The cross-sectional diameter of the tube used was approximately three-eighths inch, while its circumferential diameter was one and one-half inches.* The volume liquid displacement for the complete system (needle to copper tube, one-eighth inch O.D., to pet cock to Bourdon tube), between 0 and 300 mm. Hg pressure, was 0.1 cubic centimeter. By this system a linear relationship between pressure and mirror movement could be maintained from 0 to 300 mm. Hg pressure. Although the sensitivity of this method was much lower than that obtained by Hamilton's manometer, accuracy was maintained even at the higher blood pressure levels. The indicated pulse pressures of normal nembutalized rats were usually of the order of 5 to 15 mm. when pressures were taken from the femoral artery using a 23-gauge needle as a cannula.

RESULTS

Deviations of Observed Readings in Normal Rats on the Same Day and on Different Days Under Normal and Heated Conditions by Use of Tail Method.—Six rats were trained and the blood pressure was measured from the tail without warming the animal. Immediately after attempts were made to determine the blood pressure, the rat was placed in a carton container heated to the appropriate temperature by electric lamps. At the desired time it was removed from the carton box, and the blood pressure was again measured. The animal, as indicated in Table I, was allowed to remain at room temperature for the desired time, the blood pressure was determined, and the rat was inserted into the next carton box of desired temperature. The readings obtained are charted in Table I.

These results indicate:

1. The general unresponsiveness (no apparent volume change in the tail) of normal unanesthetized rats unless heated.

2. The wide variation of "normal" blood pressure of normal animals when heated in the same way on different days.

3. The wide variation of response to given temperature changes of the same rat on different days.

Comparison of Simultaneously Observed Blood Pressures by Use of Tail and Foot Methods in Unheated, Heated and Cooled, Normal and Operated Animals.—Each animal used was placed in the rat holder adapted for foot blood pressure determination so that readings could be made simultaneously on the tail and on the foot (see Fig. 2). When warmed, the animals were heated by means of a portable heat lamp, so adjusted as not to reflect or shine directly into the apertures of the photocells of either machine.

The cuffs used in the tail method and the foot method were of such a diameter that they were proportional to the size of the appropriate appendage, that is, for the tail cuff, a 9 mm. wide, 9 cm. long cuff was used, while on the foot, where the cross-sectional diameter is smaller, a 5 mm. wide 7 cm. long cuff was used. Both cuffs were of the same thickness rubber drawn in the same speed from the same Latex (two-dip, 5 inches a minute).

In all cases, readings recorded were the average either of two or three readings. Sensitivities of both machines to volume change were the same. The results obtained in four rats picked at random are given in Table II.

These four experiments, which are a few of many such trials, indicate the following:

1. Not all rats gave volume changes in the tail when normal (unheated). In all cases (approximately 10,000 readings) blood pressure recordings (volume changes) were and have been obtained in using the foot method without heating the animal.

2. When warmed, those animals which gave no detectable volume change in the tail gradually gave increasingly larger volume changes in the tail at higher and higher blood pressure levels. When cooled by packing the metal portion of the cage with a cold water bag or ice, readings and volume changes gradually diminished until both were lost.

3. Readings were obtained continuously by use of the foot method with a definite rise of blood pressure due to heating. An increase of volume change was also observed. Heated rats are therefore no longer "normal" animals in reference to blood pressure.

4. The indicated blood pressure in the tail is not necessarily related to the indicated blood pressure in the foot in unheated unanesthetized animals, although in the heated animals the indicated blood pressures of both methods agree within the experimental error of the methods.

Comparison of Observed Readings by Direct Femoral Puncture and by Tail and Foot Methods in Nembutalized Animals, and the Effect of Nembutal on "Vasoconstrictor Reflex."—Three previously trained animals were used in this experiment. Before anesthetization, the blood pressure was measured both by the tail procedure and by the foot procedure simultaneously. The animal was then anesthetized intraperitoneally with nembutal, 5 mg. per 100 grams, and the blood pressure was followed as the anesthetic took effect. After anesthesia

0, No readings obtainable.

-, Not done.

was complete (third stage), the blood pressures were taken and the direct puncture instrument was then cannulated to the femoral artery on the right leg. The left foot was used to follow the blood pressure by the foot technique, while simultaneously observing the blood pressure in the tail.

In these three animals, obstruction of the upper respiratory passages due to the anesthetic used⁷ was not encountered, and tracheotomy was not necessary.

In these three animals, the effect of anesthesia on the vasoconstrictor reflex is demonstrated (Table III). In the third animal various substances (pressor or depressor) were injected into the femoral vein and the blood pressure was followed by all three methods.

The results of these experiments indicate:

1. Normal unheated unanesthetized rats which gave no volume changes in the tail (and, therefore, presumably no blood pressure) when anesthetized with nembutal gradually gave volume changes in the tail as the degree of anesthesia increased without application of heat to the animal. It is, therefore, concluded that both anesthetization and heating of the animal have the same effect on the "vasoconstrictor reflex" in regard to the volume change and the indicated blood pressure in the tail. It therefore becomes apparent why agreement between the tail method and the direct puncture method is obtained in the anesthetized animal,^{5,7} but it does not necessarily mean that there is agreement between the indicated blood pressure using the tail method and the systemic blood pressure in the unanesthetized animal.

2. Agreement of indicated blood pressures obtained by the foot method, tail method, and direct puncture method in the anesthetized animal was within the limits of the experimental errors.

SUMMARY

1. A comparison of indicated blood pressures as obtained by use of the foot and the tail has been made in both normal unheated and operated unheated animals. The agreement of the values obtained has been very poor, although both methods depend on the same principle for determination of blood pressure; that is, the change in volume in the appropriate appendage is observed by means of a photocell system before and after constriction of a sphygmometer cuff applied to the specific appendage.

2. The blood pressure of normal unheated rats as measured by the tail method has varied between 50 and 130 mm. where a volume change in the tail occurred. (Proskauer and co-workers⁶ have reported a value of 65 to 95 mm. of Hg.) In very normal unheated animals, no volume change and, therefore, presumably no blood pressure could be detected. In all cases volume changes were observed when using the foot. The average blood pressure obtained in a group of seventeen normal unheated rats picked at random was 117 ± 8 mm. Hg.¹ This value is in good agreement with those obtained by direct puncture as reported by Schroeder⁷ for normal anesthetized rats.

3. It was observed that in the tail of the normal unanesthetized animal, in cases where there was no volume change unless heated, the volume change gradually increased with increased heat applied to the rat, and that these

volume changes occurred at concurrently higher blood pressure levels. Attempts to standardize the amount and the rate of heating applied to the rat were made with no success. By using the foot method, readings were obtained without the application of heat. In the foot, as heat was applied, the volume change also increased but at a much lower rate, while the blood pressure rose from the level obtained in the unheated normal animal. It is, therefore, apparent that normal heated animals are no longer "normal" in regard to blood pressure. It is also apparent that the blood pressure in the tail, as indicated by the volume change principle, is not directly related to the systemic blood pressure in the unheated unanesthetized rat, although under abnormal conditions (heating or anesthesia) a relationship between indicated foot blood pressures and the indicated tail blood pressures was obtained.

4. Under the influence of anesthesia volume changes in the tail could be easily obtained without the application of heat, and agreement of all three methods was fairly good when simultaneous blood pressure readings were taken by tail, foot, and direct puncture.

The authors are indebted to Mr. Robert C. Annen and to Mr. Clifford Blauvelt for their contribution to the adaptation of the direct puncture instrument. We are also grateful to Mr. Leslie McWilliam for the photographs.

THE DIAGNOSIS OF PANCREATIC DISEASE BY ENZYME TESTS

LESTER M. MORRISON, M.D.

LOS ANGELES, CALIF.

THE clinician has long found the diagnosis and treatment of diseases of the pancreas to be among the most difficult and uncertain of all diseases. This has been adjudged partly to be due to (1) the lack or obscurity of symptoms in early or moderately advanced stages of pancreatic disease clinically, and (2) the complexity of pancreatic tests and their impracticability for the practicing physician, biochemically.

In this paper I report the results of studies carried out from a series of patients seen in gastroenterologic practice which have been used as an aid in the diagnosis and treatment of diseases of the pancreas. This study was undertaken with the view of utilizing some procedure which would aid in establishing a diagnosis of pancreatic disease.

The American Gastroenterological Association¹ appointed a committee to study the pancreatic problem. Among other reports, two extensive investigations for the committee were published by two groups of investigators, one from the laboratories of the Mayo Clinic,² and one from the laboratories of the Western Reserve University School of Medicine and Hospital.³

I therefore believed it might be of interest to describe additional pancreatic studies in gastrointestinal diseases in the attempt to explore further the practicability and reliability of pancreatic diagnostic procedures.

These studies do not touch upon acute pancreatitis, which is in the nature of an acute surgical emergency, but rather on diseases of the pancreas such as cancer, stone, and chronic inflammation, as well as on disturbances of the pancreas caused by primary diseases of contiguous organs.

Extensive evidence has now been accumulated by surgeons and pathologists alike⁴ that dyspepsia is often the primary or secondary expression of chronic pancreatitis. For example, Rich and Duff found "repeated focal necrosis, focal hemorrhages, and epithelial metaplasia" in routine pancreatic examinations during autopsies at the Johns Hopkins Hospital.⁵ These findings have been duplicated by other observers.⁶ Osler also drew attention to this fact and stated that the confusion existing on the subject was due to the "personal equation of the laboratory workers."⁷

Clinicians attempting an analysis of the role of chronic pancreatitis in causing dyspepsia are represented by Koehler,⁸ who found that 26 per cent of his series of patients suffering from "functional indigestions" showed duodenal amylase deficiency. Rivers⁹ survey suggests a similar conclusion.

¹From the Departments of Internal Medicine and Experimental Medicine, College of Medical Evangelists.

²Presented before the meeting of the Western Society for Clinical Research, San Francisco, Nov. 2, 1916.

³Received for publication, July 31, 1916.

Although pancreatic stones are rarely diagnosed by the clinician during life, the studies of Ludin¹⁰ have shown that routine x-ray examinations of 542 pancreases correlated with histologic study revealed concretions in 5 per cent of the cases. These concretions varied in size from the head of a pin to that of a hazelnut. Snell and Comfort,¹¹ Moss and Freis,¹² and others have shown the value of pancreatic functional tests in patients with pancreatic lithiasis.

In reference to the condition described as "pancreatic edema," many surgeons have described the frequency of this condition at operation.¹³ Archibald in 1913 was one of the first surgeons to report a series of patients suffering from attacks of acute epigastric pain in whom operation revealed only pancreatic edema.¹⁴ Pratt,¹⁵ a lifelong worker in pancreatic diseases, described the accumulative evidence which indicates that attacks of epigastric pain are due, not infrequently, to mild acute pancreatic lesions.

Experienced surgeons like Elman,¹⁶ Cole,^{13b} Demel,¹⁷ Loeffler,¹⁸ and others too numerous to mention all have reported series of patients suffering from attacks of epigastric pain in whom careful surgical exploration revealed diffuse edema of the pancreas, without evidence of necrosis or hemorrhage.

Pratt¹⁵ has emphasized the fact that in patients where the symptoms are indicative of gall bladder disease, or where the clinical picture is that of gallstones and the cholecystograms are negative, pancreatic disease is frequently present.

The need for study of pancreatic disorders has thus been keenly felt for some time.

Since Einhorn's introduction of the duodenal bucket in 1910²⁰ numerous investigators²¹⁻²⁶ have reported the results of their procedures in the testing of pancreatic function. However, the recent studies of Free and Myers²⁶ present such a comprehensive and improved system of technique that I have used their methods in testing pancreatic function.

METHOD

A series of eight subjects in good health who were free of any gastrointestinal signs or symptoms were selected for normal controls. They consisted of five women and three men ranging from 20 to 58 years of age. Duodenal drainages and tests were routinely performed in all subjects on an empty stomach in the morning. The fasting duodenal secretion was first extracted and then one ounce of warm olive oil was injected through the tube into the duodenum and retained for ten minutes. The duodenal contents were siphoned off in twenty-, forty-, and sixty-minute periods after the olive oil stimulation and each specimen was examined for proteinase, amylase, and lipase according to the methods devised by Free and Myers.²⁶ Thus twelve pancreatic functional determinations were performed at each duodenal drainage. As described in Tables I to VI, the number of duodenal drainages varied in each patient from one to five, giving a range of functional tests numbering from twelve to sixty for each subject. In all, a total of more than one thousand duodenal pancreatic tests are herein reported. Bile pigment in each diluted sample was determined by the icterus index.

CASE MATERIAL AND RESULTS

Table I shows that in over 288 pancreatic enzyme determinations taken from eight normal subjects, the average values for the fasting and twenty-, forty-, and sixty-minute periods of stimulation by olive oil were: proteinase,

3.6 mg.; amylase, 7.5 mg.; and lipase, 8 milliliters. However, it is noted that the normal variations for proteinase, amylase, and lipase are great. They range from 0.6 to 7.4 mg. in proteinase, from 0 to 17.3 mg. in amylase, and from 0 to 31.4 ml. in lipase. In these normal subjects zero readings were not found again at subsequent tests.

TABLE I. DUODENAL CONTENT ANALYSES FOR PANCREATIC ENZYMES IN EIGHT NORMAL SUBJECTS OVER TWENTY-FOUR TEST PERIODS; AVERAGE VALUES, 238 TESTS

ENZYME	FASTING	20 MIN. AFTER OLIVE OIL STIM- ULATION	40 MIN. AFTER OLIVE OIL STIM- ULATION	60 MIN. AFTER OLIVE OIL STIM- ULATION	MINIMUM VARIATION	MAXIMUM VARIATION
Proteinase*	2.5	3.0	4.2	4.9	0.6	7.4

Lipase‡	4.8	5.7	6.8	15.0	0	31.4

*Milligrams tyrosine equivalent.

†Milligrams glucose equivalent.

‡Milliliters 0.05 N sodium hydroxide equivalent.

Table II shows that in over sixteen pancreatic enzyme determinations taken from eight subjects with "functional" or nonorganic disturbances of the upper gastrointestinal tract, the average values for the fasting and twenty- and sixty-minute stimulation intervals were: proteinase, 2.0 mg.; amylase, 4.3 mg.; and lipase, 4.0 milliliters. The individual variations in "functional" disorders are considerable. They range from 0.2 to 3.8 mg. in proteinase, from 0.6 to 8.5 mg. in amylase, and from 0 to 8.5 ml. in lipase. Zero findings were not repeated at subsequent determinations. These eight subjects were diagnosed as having upper digestive tract dyspepsia, six from gastrointestinal neuroses and two from the postcholecystectomy syndrome.

TABLE II. DUODENAL CONTENT ANALYSES FOR PANCREATIC ENZYMES IN EIGHT PATIENTS WITH "FUNCTIONAL" OR NONORGANIC DISORDERS OF THE UPPER GASTROINTESTINAL TRACT; AVERAGE VALUES FOR SIXTEEN TESTING PERIODS, 192 TESTS

ENZYME	FASTING	20 MIN. AFTER OLIVE OIL STIM- ULATION	40 MIN. AFTER OLIVE OIL STIM- ULATION	60 MIN. AFTER OLIVE OIL STIM- ULATION	MINIMUM VARIATION	MAXIMUM VARIATION
Proteinase*	1.3	1.8	2.2	2.7	0.2	3.8
Amylase†	2.9	4.0	4.9	5.6	0.6	8.5
Lipase‡	2.9	3.4	4.5	5.1	0	8.5

*Milligrams tyrosine equivalent.

†Milligrams glucose equivalent.

‡Milliliters 0.05 N sodium hydroxide equivalent.

Table III shows that in twenty subjects suffering from organic diseases of the upper digestive tract, the average values for all the intervals previously described were: proteinase, 1.3 mg.; amylase, 3.7 mg.; and lipase, 3.6 milliliters. The individual test readings for enzymes here also are very variable. The range for proteinase is from 0 to 5.6 mg.; for amylase, from 0 to 10.4 mg.; and for lipase, from 0 to 13.6 milliliters. In contrast with the normal controls and the "functional" cases, if zero readings were obtained and found again at subsequent tests, extensive involvement of the pancreas by cancer was present as occurred in the three cases of cancer of the pancreas (Table V, Cases

TABLE III. DUODENAL CONTENT ANALYSES FOR PANCREATIC ENZYMES IN TWENTY PATIENTS WITH ORGANIC DISEASES OF THE UPPER GASTROINTESTINAL TRACT; AVERAGE VALUES FOR FORTY-THREE TESTING PERIODS, 510 TESTS

ENZYME	FASTING	20 MIN. AFTER OLIVE OIL STIM- ULATION	40 MIN. AFTER OLIVE OIL STIM- ULATION	60 MIN. AFTER OLIVE OIL STIM- ULATION	MINIMUM VARIATION	MAXIMUM VARIATION
Proteinase*	0.7	1.2	1.5	1.7	0	5.6

‡Milliliters 0.05 N sodium hydroxide equivalent.

3, 4, and 18). If near zero readings were consistently obtained, particularly in proteinase, extensive disease of the pancreas was found such as in the three cases of pancreatic cirrhosis with or without lithiasis (Table V, Cases 2, 6, and 7).

COMMENT

The twenty patients with organic disease listed in Tables III and VI consisted of three patients with carcinoma of the pancreas, two with cholelithiasis, one with choledocholithiasis, one with pancreatic lithiasis, two with pancreatic cirrhosis (diagnosed at operation), three with cirrhosis of the liver, three with duodenal ulcer, one with gastric ulcer, and one with infectious hepatitis and cholangitis, carcinoma of the pyloric end of the stomach, carcinoma of the gall bladder and bile ducts, and nontropical sprue, respectively.

Table IV compares the total average enzyme values for all interval readings found in normal subjects with those of functional and organic diseases of the upper digestive tract. It is seen that the respective average readings in the "normal" controls and the "functional" cases appear to be clearly defined. However, the difference between the average readings of the "functional" and those of the "organic" diseases seems small. This lack of contrast appears to be due to the inclusion of a group of cases under "organic" cases in which the pancreas itself was not primarily involved. Cases of gastric and duodenal ulcer or cholelithiasis are examples. On the other hand, when the cases in which the pancreas is involved primarily, such as by carcinoma or cirrhosis or the stone, are examined the test readings are consistently zero or very close to zero. The minimal and maximal ranges varied quite widely in any one patient in whom the pancreas was not extensively and markedly involved and rendered it impossible to determine accurately the category in which one reading placed a patient.

Percentages were not calculated since the range of variation in (1) normal subjects, (2) patients with organic disease of the upper digestive tract, and (3) patients with functional diseases of the upper digestive tract are so great that only repeated zero readings or repeated near zero readings are of diagnostic significance.

One single determination of the proteinase, amylase, or lipase values would appear to be adequate since the enzyme values were consistent in rendering the same information in one patient. This was particularly true where severe

20	Infectious epidemic hepatitis	8	1.7	4.2	4.4

primary disease of the pancreas was present, as in the three cases of carcinoma of the pancreas, each accompanied by jaundice.

In the three patients with pancreatic carcinoma the enzyme values were zero throughout for every proteinase, amylase, and lipase reading at the fasting and twenty-, forty-, and sixty-minute stimulation periods. In the case of marked pancreatic cirrhosis with or without lithiasis, the readings were all consistently close to zero. These two primary diseases of the pancreas, that is, cancer or extensive cirrhosis (with or without stone), therefore consistently gave findings of diagnostic value in the duodenal pancreatic enzyme tests.

SUMMARY

1. Over 1,000 pancreatic enzyme tests (Free and Myers²⁴) were made from the duodenal secretions in a group of normal subjects, in a group of patients with "functional," or nonorganic disease of the upper digestive tract, and in a group of patients with organic disease of the pancreas, biliary tract, stomach, or duodenum.

2. The range and mean of duodenal pancreatic enzyme tests for normal subjects and patients suffering from upper digestive tract disorders are described. Variations of test findings are very wide in both normal subjects and patients with most organic diseases of the pancreas or upper digestive tract.

3. Normal subjects as well as patients with extensive and severe pathologic involvement of the pancreas such as cancer may give zero or near zero test readings in individual duodenal pancreatic enzyme tests.

4. In patients with organic disease of the stomach or biliary tract, pancreatic duodenal enzyme tests revealed no individual distinctive or diagnostic findings. However, their group mean value was definitely lower than the comparable value in normal subjects.

5. A group of ten patients with chronic low-grade or moderate inflammation of the pancreas, as revealed at operation, had a series of duodenal pancreatic enzyme tests performed before and after operation. The duodenal enzyme study failed to show any consistently abnormal findings of diagnostic value either pre- or postoperatively.

6. In six cases of extensive involvement of the pancreas by cancer or cirrhosis with pancreatic lithiasis, 125 tests gave abnormal findings in the duodenal pancreatic enzyme tests. These abnormal findings were either zero or near zero values.

7. If a zero reading was found in the pancreatic enzyme tests of a normal subject, it was not consistently found at subsequent determinations. In the presence of advanced and extensive pancreatic disease such as cancer or cirrhosis, zero and near zero readings were found consistently at all subsequent determinations.

CONCLUSION

Extensive and advanced disease of the pancreas such as cancer or cirrhosis with lithiasis gave repeated zero or near zero readings in the duodenal pan-

creatic enzyme tests. Pancreatic enzyme tests are useful in diagnosing advanced and extensive disease of the pancreas.

For the opportunity of seeing patients in private consultation, grateful acknowledgment is made to: Dr. Burrill B. Crohn (for Case 9, nontropical sprue); Dr. Rudolph Schindler (for Case 6, pancreatic lithiasis, calcification, and pancreatic cirrhosis); Dr. Moses Behrend (for Case 2, pancreatic cirrhosis); Dr. W. Wayne Babcock (for Case 10, choledocholithiasis; and Case 8, biliary cirrhosis and choledocholithiasis); and Dr. W. Emery Burnett (for Case 7, hepatic cirrhosis).

INTRAVENOUSLY ADMINISTERED GELATIN—A TOXICITY STUDY

MILTON J. VANDER BROOK, PH.D., STANLEY C. LYSTER, BOYD E. GRAHAM, B.S.,
NOEL E. POMEROY, AND GEORGE F. CARTLAND, PH.D.

KALAMAZOO, MICH.

IT IS generally recognized that an infusion of blood or plasma is the most effective means of compensating for fluid loss which occurs in hemorrhage and shock of various types. Since blood and plasma are not always immediately at hand, however, it is desirable that a plasma substitute be found which is innocuous, effective, inexpensive, and readily available.

The recent literature records that substitutes somewhat less effective than plasma in restoring circulating fluid volume, but much more effective than crystalloidal solutions, are aqueous solutions of macromolecular substances, such as gelatin, gum arabic, pectin, ovalbumin, polyvinyl alcohol, and methyl cellulose. Gelatin¹⁻²⁰ appears to possess desirable characteristics to a greater degree than most of the other macromolecular substances mentioned.

Observations in this laboratory on the toxic effects in animals of infused gelatin solutions which were subsequently tested for efficacy by laboratory animal experimentation^{11, 18} and clinical investigation^{15, 16, 19, 20} confirm the findings of others in many respects. Some of the undesirable properties of gelatin, however, such as impairment of the production of plasma proteins and hemoglobin,¹⁷ and degenerative and proliferative arterial lesions of the sclerosing type reported by Heuper⁶ in dogs, are apparently observed only when large amounts of highly concentrated gelatin solution are repeatedly infused into the blood stream of intact animals, thus placing a severe strain on the circulatory system. When a 5 to 8 per cent gelatin solution is infused into dogs or human subjects suffering fluid loss from hemorrhagic, traumatic, or burn shock in amounts approximately equal to the amount of fluid which has escaped, such untoward effects have not been reported.

The experiments herewith presented were designed to test whether or not the circulatory system of dogs under the stress of light anesthesia and severe blood loss could tolerate large quantities of 5 per cent gelatin administered in divided doses over a period of several weeks.

The solutions of gelatin* were prepared by electrodialysis of osseous calcium gelatinate. The 5 per cent solutions preserved with phenyl-mercuric borate, 1:25,000, were degraded by autoclaving to obtain a mean molecular weight of 20,000 (number average). These solutions were nonantigenic and nonpyrogenic.

EXPERIMENTAL

Nine mongrel dogs supplied with a high protein diet supplemented with raw liver were bled of 29 to 54 per cent of their estimated blood volume at weekly intervals for periods of two to thirteen weeks (average, seven weeks). The blood, aseptically removed from the

*Supplied by Dr. S. H. Eppstein, of these laboratories.

exposed jugular veins under light ether anesthesia, was replaced at the same site by infusion of 5 per cent gelatin solution in amounts equal to 80 per cent of the blood removed. Control animals consisted of two dogs bled just as severely as those mentioned, but with no parenteral fluid replacement, and twenty apparently healthy dogs with no treatment whatsoever.

At intervals determinations of plasma protein and gelatin concentration in plasma, urine, and aqueous tissue extracts* were made by the method of Waters⁴ which makes use of the fact that gelatin is not precipitated by trichloroacetic acid but is precipitated by acid tungstate. Plasma protein nitrogen was thus determined by the usual Kjeldahl technique on the trichloroacetic acid precipitate and gelatin nitrogen by difference between nitrogen contents of the acid tungstate and trichloroacetic acid precipitates. The usual methods were employed for determination of red cell volume, hemoglobin, red cell count, white cell count, and sedimentation rate.²²

Extensive pathologic studies on tissues of experimental and control dogs were done.[†]

On one of the nine dogs, a celiotomy was performed both prior to and one week after a series of six hemorrhages and gelatin infusions. Liver tissue was removed and examined at these times. Seven weeks later this dog was sacrificed and the tissues examined. A second dog was bled and infused with gelatin five times after a celiotomy had been performed for removal of liver tissue. He was sacrificed two weeks after the last hemorrhage and infusion.

RESULTS

Repeated massive hemorrhages and infusions of purified gelatin in dogs under the conditions described produced no notable changes in deportment or body weight (Table I). The only gross disturbance observed was the formation of thrombi at the sites of injection in some dogs which Patek and co-workers²⁴ have demonstrated to be due to the mercurial preservative employed. Histologic examination of the jugular veins at autopsy revealed no changes in the intima. Considerable scar tissue formed about these veins, presumably due to the surgery involved, and fluid regurgitated into surrounding tissue when the needle was withdrawn. Wound healing was not impaired. There was no indication of the presence of pyrogenic or antigenic material in the gelatin.

*Weighed quantities of kidney and liver from both control and gelatin-infused dogs were thoroughly macerated with saline in a Waring blender. Gelatin in the supernatant fluid was determined by the method used for plasma gelatin.

†By Dr. Walter Schiller and Dr. Bruno Volk.

Examination of blood and plasma during the experimental period revealed that the changes observed in hemoglobin and plasma protein levels could be accounted for by the severe hemorrhage alone and were not markedly affected by the infused gelatin. (Tables II and III).

168	797	12	1.0

The sedimentation rate of erythrocytes was greatly accelerated by the infused gelatin. In most instances the sedimentation rate decreased approximately at the same rate as the gelatin concentration in the plasma decreased. In all instances, the rate had returned to normal the following week (Table III).

Plasma gelatin determinations revealed the presence of approximately 80 per cent of that infused at one-fourth hour after infusion, 50 per cent at four hours, and 25 per cent at sixteen hours. Urine gelatin determinations revealed that only 37 to 62 per cent of the gelatin infused was excreted unchanged (Table IV). This occurred within twenty-four hours. Gelatin determinations on aqueous extracts of the liver and kidneys of one dog at autopsy eight days after thirteen infusions indicated that there was no free gelatin stored in these organs.

TABLE IV. RATE OF APPEARANCE OF GELATIN IN URINE FOR THREE SUCCESSIVE WEEKS (DATA FROM DOG 3)

16-40	0.0				
Total excreted	61.5		37.1		57.0

Observations at autopsy revealed no gross pathology, except for scar tissue and thrombi in some instances at the sites of bleeding and gelatin infusion as noted previously.

Histologic examination of the heart, coronary vessels, aorta, carotid arteries, jugular veins, and renal arteries showed, in some instances, changes attributable only to prior disease. There was no vacuolization or subendothelial edema of the arteries and arterioles. Sections of the trachea, lungs, stomach, intestines, spleen, gall bladder, adrenals, striated muscle, brain, meninges, and gonads likewise showed no changes attributable to gelatin.

The parenchyma of the liver was normal. Many of the Kupffer cells, however, in all gelatin-infused dogs contained sudanophile droplets. Those in the areas of the acini around the periportal fields were most affected. The Kupffer cells in nine of twenty-four control sections of liver tissue showed moderate fat staining. The Kupffer cells of human liver, according to Levine,²⁸ normally contain neutral fat. The Kupffer cells of one of the dogs from which a portion of the liver was removed prior to gelatin infusions were fat-free. Immediately after completion of the series of infusions, the Kupffer cells were loaded with sudanophile droplets. At autopsy, seven weeks later, the same condition obtained. The nuclei of the Kupffer cells appeared normal in all cases.

Histologic examination of the kidneys of gelatin-infused dogs showed, in some instances, slight departures from the normal. The epithelial cells of the tubules of the proximal convolutions were sometimes swollen and occasionally vacuolated. Since gelatin is cleared through the kidneys, it is conceivable that in some animals it may have been responsible for the slight pathology observed.

CONCLUSIONS

A highly purified and highly degraded 5 per cent gelatin solution prepared especially for intravenous therapy in human subjects was well tolerated by dogs when given repeatedly for several weeks in amounts commensurate with the fluid lost by hemorrhage. The only morphological pathology which might be attributable to gelatin in this series of dogs was the presence or increase of sudanophile droplets in the Kupffer cells. The significance of such a change is not known. It appears that the function of the Kupffer cells was not materially altered. None of our dogs developed infection of the respiratory tract or at the sites of bleeding and infusion.

The vascular pathology described by Hueper⁶ was not observed in our series. Although Morehead and Little²¹ found degenerative and reparative changes in the vascular system of their gelatin-infused dogs, they concluded that the lesions were not due to gelatin since similar changes were present in their control series.

Of the blood constants determined, only the sedimentation rate was altered by gelatin. This phenomenon is common to all macromolecular substances and occurs also when plasma protein concentrations are elevated. Gelatin did not interfere with the formation of hemoglobin or plasma protein, both of which were partially depleted at each hemorrhage, when infused weekly for periods as long as three months.

Gelatin appears not to be stored in the liver or kidneys. A major portion is excreted by the latter. The fate of the balance is unknown.

SUMMARY

1. Gelatin solutions prepared for intravenous therapy proved innocuous to dogs when administered intravenously following repeated massive hemorrhages over a period of several weeks.

2. Vascular pathology was absent. The presence or increase of sudanophile droplets in the Kupffer cells was the only morphologic change attributable to gelatin.

3. Gelatin did not interfere with the formation of hemoglobin or plasma protein and appeared not to be stored in the liver or kidneys. A major portion was excreted by the kidneys.

ATTEMPTS AT THE EXPERIMENTAL PRODUCTION OF ARTHRITIS

RALPH PEMBERTON, M.D., JOHN EIMAN, M.D., F. M. SIMMONS PATTERSON, M.D.,
AND ELEANOR A. STACKHOUS
PHILADELPHIA, PA.

A RELATIONSHIP of the endocrine system to the phenomena of arthritis has long been suspected. Even before the development of modern endocrinology, it was recognized that the menopause seemed to have a significant influence upon the development of hypertrophic or osteoarthritis, and the term arthritis of the menopause appears in the literature as far back as 1855.

Recently an attempt has been made by one of us (R. P.), in conjunction with Scull, to integrate known and suspected factors within the neuroendocrine field in the pathogenesis of rheumatic disorders.¹

Efforts have been made to simulate in experimental animals the phenomena of arthritis in some of its manifestations by means of injection of hormonal material, by the ablation of certain hormone-yielding organs, and by other steps of the kind. Among the most significant studies in this connection have been those of the Silberbergs² who have succeeded in producing some of the pathologic picture of hypertrophic or osteoarthritis in experimental animals by injection of extracts of the pituitary. Another attempt of the same general nature has been made by Selye,³ who describes the induction of a number of phenomena characteristic of the arthritic state as the result of the injection of desoxycorticosterone acetate with the exhibition of certain other concomitant influences.

Selye³ reports that the administration of desoxycorticosterone acetate in comparatively large doses causes the formation of "Aschoff bodies in the heart and the presence of periarteritis nodosa, a condition occasionally seen in man following an attack of rheumatic fever. Since in addition choreiform twitches and a few rare cases of arthritis were encountered in desoxycorticosterone acetate treated animals, it may be said that all the elements of the complex rheumatic syndrome were reproduced in experimental animals."

He further states, "The arthritic lesions, which are rarely seen in the intact desoxycorticosterone acetate treated rat, develop with great frequency in similarly treated thyroidectomized or adrenalectomized animals, especially if these are kept in cold surroundings."

He also says, "Previous experiments revealed that unilateral nephrectomy and sodium chloride treatment increase the sensitivity of rats to many overdosage effects of desoxycorticosterone acetate." In his experiments "all animals were sensitized by ablation of the left kidney 5 days before injections were started and given 1% NaCl to drink beginning on the day of operation."

It is obvious that importance attaches to conclusions of this nature and it was therefore decided to repeat, so far as possible, Selye's experiments.

From the Abington Memorial Hospital, Abington, Pa.

The expenses of this investigation were met, in part, by a grant in the name of Francis Allison Poultney.

Received for publication, May 5, 1947.

Experiment 1 (Divided Into Three Groups).—

Group A: Eight female albino rats weighing 20 grams each were put on Fox chow plus 1 per cent NaCl to drink, and six of them were given injections of 3 mg. desoxycorticosterone acetate* twice daily for forty-two days. To serve as controls, two received no injections. The temperature of the animal room varied from 55 to 80° F. Three of the six injected rats showed some redness and swelling of the hind feet and knee joints eleven to eighteen days after injection. This subsided and reoccurred from time to time, disappearing before autopsy. The two controls showed no gross lesions. At autopsy six of the eight rats, including both controls, were found to have parasitic infection of the livers, the parasite being a strobilocerens of the *Taenia Taeniaformis*, a common

Fig 1.—One articular surface of experimentally induced arthritis shows focal destruction of cartilage and underlying bone. The normal tissues are replaced by seminecrotic material, proliferating cartilage, and fibroblasts.

tapeworm of the domestic cat, the intermediate host being rats and mice. Sections were made of the hind legs and feet. The three affected rats showing gross swelling revealed microscopic joint changes. These were slight proliferation of the capsule with the lining of the cells piled up over a small ulcer in some places; loss of cartilage; a proliferation of fibroblasts replacing the ulcerated cartilage; marked focal destruction of articular cartilage on both articular surfaces; and adhesions extending from one ulcerated area to the other with loose connective tissue replacement (Fig. 1).

*The desoxycorticosterone acetate used in these experiments was made available through the courtesy of Dr. Edward Henderson, Director, Division of Clinical Research, Schering Corporation, Bloomfield, N. J.

Of the two control rats receiving no injections, one leg joint of one rat showed one-third of the joint surface of the cartilage to be replaced by irregular masses of proliferating connective tissue.

Group B: A similar group of eight rats was given Fox chow and plain water to drink and was injected identically with Group A, in the same room, at the same time, for the same length of time, to determine whether the absence of 1 per cent salt made the animals more or less susceptible to arthritis. There was never any gross redness or swelling. One injected rat died. One control was not sacrificed. At autopsy, of the five injected rats and one control, three, including the control, were found to be infected with parasites. Sections of the hind legs were made and only one of the injected rats showed any joint change. In this animal one joint surface showed a necrotic area in the cartilage.

Within the joint cavity of another joint, seminecrotic tissue was observed to be attached to the synovia. The control rat was negative.

Group C: At the same time eight rats varying in weight from 25 to 86 grams were put on Fox chow plus 1 per cent NaCl, and four were given injections. The remainder served as controls. All were placed in a room without heat where the temperature was 40 to 55° C. The four injected rats died in a few days and four more, weighing 116 to 122 grams, were substituted. The controls which did not succumb weighed 82 to 86 grams. The experiment was discontinued after thirty-five days, since there was no gross redness or swelling. At autopsy no liver parasites were found. One control rat and the four injected rats were sectioned. One test rat showed proliferation of connective tissue from the synovia into one joint cavity.

It may be concluded from this experiment that:

1. Young rats, overdosed with desoxycholesterone acetate and given 1 per cent NaCl to drink, showed joint changes in 50 per cent of the experimental animals, somewhat resembling certain phases of hypertrophic or osteoarthritis found in man. Some joint change of similar nature was seen in one joint of one control.

2. The subjection of experimental rats to environmental cold, as described, does not substantiate Selye's findings, since no evidence of gross swelling or crippling resulted.

3. The rats not ingesting salt showed no marked incidence of gross or microscopic changes in the joints.

Experiment 2.—This experiment was carried out on mononephrectomized and bilateral adrenalectomized rats. The following steps were employed in each operative procedure:

1. The rat was anesthetized with ether.
2. The rat under anesthesia was secured to an operative board of soft wood by means of rubber bands looped about the feet and over hooks which were attached to the board.
3. The operative area was clipped with scissors and then shaved.
4. The skin of the operative site was painted with tincture of metaphen.
5. Sterile draping of the operative site was performed.

6. The surgeon used sterile gloves after thoroughly scrubbing his hands with soap and water.

7. Sterile instruments were used throughout.

8. After the operation had been completed, the rat was kept in a warm cage until out of anesthesia.

The surgical technique employed in each experiment is now given in detail.

Technique of Unilateral Nephrectomy and Bilateral Adrenalectomy: Ether anesthesia was used and the rats were placed in a prone position. A dorsal midline incision was made through the skin at the level of the kidneys. The subcutaneous fascia was incised on the right, exposing the muscle. A longitudinal incision was then made along the lateral border of the right dorsal muscle mass. The muscle was retracted medially and the kidney and adrenal exposed. The right kidney and adrenal were delivered. The kidney pedicle was ligated with No. 00 plain catgut and the kidney and adrenal excised. Similar exposure was then made on the left side. The kidney was delivered and the adrenal was displaced upward, detached from the upper pole of the kidney, and removed. The kidney was returned to its anatomic position. The skin was then closed with interrupted fine silk sutures.

Thirteen female albino rats weighing from 40 to 50 grams were mononephrectomized, and seven of these were bilaterally adrenalectomized. They were given 1 per cent NaCl to drink and Fox chow. Five days later, weighing 65 to 90 grams, they were given injections of 3 mg. of desoxycorticosterone acetate twice daily for twenty-eight days. This was given to the seven adrenalectomized, mononephrectomized rats and to four of the six mononephrectomized rats. The mononephrectomized and one intact rat were kept as controls, receiving no injections. They were all kept in a warm room.

No redness or gross swelling was observed. At autopsy none of the rats showed parasitic infestation. The hind legs were examined microscopically with the following results:

1. Two of the seven adrenalectomized, mononephrectomized rats showed some joint changes.

2. One of the four mononephrectomized rats developed a joint showing practically complete obliteration of the joint cavity due to adhesions of adult connective tissue between both articular surfaces. The same joint showed destruction, and connective tissue replacement, of articular cartilage.

3. One control rat, nephrectomized, showed slight absorption of cartilage and slight proliferation of endothelial cells at the attachment of the synovia.

It is evident from these experiments that the operations discussed did not contribute further to the development of arthritis. Normal rats overdosed with desoxycorticosterone acetate showed more evidence of joint changes than did those operated upon.

Experiment 3.—Eight rats were mononephrectomized and thyroidectomized as follows:

The previously described technique for unilateral nephrectomy was observed. The animal was then placed in the dorsal position for *thyroidectomy*. The head of the animal was kept in extension by means of a rubber band looped over the upper incisors. A ventral midline incision was made in the neck. The salivary glands were freed at the midline and retracted laterally. The sternohyoid muscle was divided in the midline. The thyroid was exposed by careful, blunt dissection with a small curved hemostat. The gland was grasped with

tooth forceps, and while retraction was exerted upward and laterally the gland was dissected free from its attachments by means of a needle. Bleeding was negligible when the gland was removed by this technique. The skin was then closed with interrupted fine silk.

Five days after operation, the eight rats were injected with 3 mg. of desoxycorticosterone acetate twice daily for a total of ninety injections.

None of these rats showed any gross redness or swelling. One died at five weeks. Since these rats showed no gross evidence of arthritis, it was decided to add one more stress in the form of an injection of bacterin or bacterial toxin. This, when given to human beings, often causes a systemic reaction such as chills and fever. With this thought in mind, it was decided to subject these operated rats, overdosed with desoxycorticosterone acetate, to increasing doses of whole typhoid bacterin and serobacterin.

The remaining seven rats were divided into three groups:

Two rats were given .3 ml. of typhoid whole bacterin.

Three rats were given .3 ml. of serobacterin typhoid.

Two rats were not given any bacterin, being left as controls.

Two normal rats were used as controls on the bacterin alone, one receiving the serobacterin, the other, the whole bacterin. The doses of bacterin were given at five-day intervals and increased to 1 ml., the schedule of dosage being .3, .6, .8, 1 ml., and 1 ml. Since these injections did not seem to have any gross effect on the health of the rats, all were sacrificed and autopsied.

The two control rats, receiving typhoid bacterin *only*, showed no joint changes.

Of the three remaining rats, only one of which had received typhoid bacterin, all showed extensive ulcerations and connective tissue replacement of articular cartilage by fairly adult connective tissue.

The two control rats, receiving typhoid bacterin *only*, showed no joint changes.

This experiment with mononephrectomized, thyroidectomized rats subjected to overdosage of desoxycorticosterone acetate and the addition of typhoid bacterin did not increase the extent or incidence of joint changes.

Experiment 4.—Another group of fifteen rats weighing 30 grams was treated as follows:

Seven were mononephrectomized as previously described, and ovariectomized.

Four were ovariectomized. In one the testicles were removed.

Technique of Bilateral Oophorectomy: Ether anesthesia was used and the rats were placed in a prone position. The right ovary was exposed through the thin muscle wall just below the dorsal muscle mass. Hemostasis was then insured by ligation of the upper horn of the uterus on the right side with No. 00 plain catgut. The right ovary and the oviduct were then removed. A similar technique was used to remove the left ovary and oviduct. The skin incision was closed with interrupted fine silk sutures.

Three of the fifteen rats were left intact as controls. All were put on Fox chow and 1 per cent NaCl. Five days after operation all were given 3 mg. of desoxyeortieosterone acetate twice daily for thirty days, a total of sixty injections.

The rats gained weight and showed no gross evidence of arthritis. All were sacrificed and autopsied. There was no parasitic infection of the livers.

One rat which had a stitch abscess for twenty days before the infected stitch was removed and the lesion healed was watched especially to see if it would show any joint involvement due to the added stress of infection; it did not, however, and microscopic findings of its joints were negative.

The results of this experiment were:

Three of the seven mononephrectomized, gonectomized rats had some minor changes of the cartilage and underlying bone of the leg joints.

Two of the five ovariectomized rats had a few small foci of erosion of articular cartilage extending down to the bone.

Two of the three control rats, having no operations, showed focal ulcerations or erosion of cartilage in some places extending down to the bone.

This experiment reveals that the operative procedures of mononephrectomy and ovariectomy, or ovariectomy alone, do not lead to joint changes resembling "rheumatic and rheumatoid conditions in man" with a frequency greater than in normal rats which are unoperated and overdosed with desoxyeorticosterone acetate.

Since the controls in these experiments showed some joint change, a food experiment was conducted.

Experiment 5.—Twenty male and twenty female rats, most of them weighing 30 to 50 grams, a few weighing up to 100 grams, were divided into four groups, five of each sex of varying weight in each group. Both sexes were included to ascertain if one sex were more prone to arthritis than the other.

Group 1 was given Fox chow plus 1 per cent of NaCl.

Group 2 was given Fox chow plus 2 per cent of NaCl.

Group 3 was given Fox chow plus plain water.

Group 4 was given no Fox chow, but bread, greens such as lettuce or celery, and water.

All groups were kept on schedule during the summer months, from June 15 to September 26, when they were sacrificed with the following results:

1. None of the rats at any time showed any gross evidence of arthritis.
2. All rats of the group on 2 per cent NaCl were stunted in growth, scaly, dirty, and emaciated. They gained weight, but slowly.
3. Twenty-three of the thirty rats eating Fox chow showed liver parasites.
4. None of the rats, male or female, of Group 1 or 2 showed any microscopic joint changes.
5. Only three of Group 3 showed any microscopic joint change, this being found in female rats only. This joint change is described as fairly extensive destruction of articular cartilage with adhesions between articular surfaces.
6. Group 4, however (not on Fox chow), showed no liver parasites, was grossly healthy, and gained weight at a normal rate, but microscopically six of seven presented joint changes.

These joint changes constituted the most marked microscopic findings of the entire group of experiments undertaken.

The changes consisted of a fairly extensive destruction of articular cartilage, ulceration, and adhesions connecting the ulcerating surfaces (Fig. 2).

Finally, reviewing all the variations carried out in these five experiments and the results obtained, the work was concluded by repeating the first experiment.

Fig. 2—One articular cartilage, in experimentally induced arthritis, shows a superficial ulcer in which the cartilage cells have been replaced by seminecrotic material.

Experiment 6.—Rats of our own raising, weighing 30 grams, were used. Several were sacrificed before beginning the experiment to see if they were free of liver parasites. The Fox chow was sterilized, as were all the cages, to eliminate, if possible, parasitic infestation.

It was decided to use two preparations of desoxyeorticosterone acetate; a 3 mg. emulsion of crystalline desoxyeorticosterone, and a 5 mg. in 1 ml. of peanut oil.

Sixteen rats weighing 30 grams were used. Eight were given 3 mg. of the emulsion twice daily. Two were kept as controls with no injections. Six were given .5 ml. intramuscularly twice daily of the oil preparation one dose in the muscle of each hind leg. All were given sterilized Fox chow and 1 per cent NaCl for drinking water. The eight rats received injections for a period of thirty-nine days, at which time injections were discontinued.

There was no gross evidence of arthritis in either test or control rats, and all were sacrificed twenty-seven days later. The six rats on oil preparation showed much edema of the hind legs and feet which was believed to be unabsorbed oil.

The rats received a total of 18 ml. per rat over a period of twenty-four days. The day after the last injection one of these rats was sacrificed and

about 7 ml. of oil were aspirated from the tissue of the hind legs and the peritoneal cavity. The remaining animals were kept on their food, plus 1 per cent salt solution for thirty-three days longer to allow for further absorption of oil and subsidence of edema.

At autopsy no liver parasites were found. Eight of the sixteen rats, one of which was a control, or 50 per cent, showed focal destruction of cartilage and ulceration of cartilage with loose connective tissue stretching across the joint cavity from ulcer to ulcer. Some of the underlying bone was seminecrotic in the oil-treated rats (Fig. 3). These joint changes were most marked in the oil-treated animals.

Fig. 3.—Focal destruction or ulceration of cartilage and underlying bone on opposing articular surfaces in experimentally induced arthritis. The ulcerated areas are joined by a band or adhesion of young connective tissue which stretches across the joint cavity.

COMMENT

It is accepted that so-called spontaneous arthritis occurs sometimes in experimental animals for reasons that are not clear. In an attempt to meet this situation efforts were made to eliminate the influence of parasitic infection which was encountered in Experiments 1 and 2. By the same token, dietetic experiments were conducted to show that experimental rats on a balanced diet do not show the arthritic changes encountered in the rats fed an unbalanced diet. Evidence has been adduced that there may be an apparently spontaneous occurrence of arthritis in rats due to a "pleuro-pneumonia-like" organism.⁴ Normal animals, however, may also harbor this organism. The animals, in the series here reported, that showed arthritis gave no clinical evidence of systemic illness and autopsy revealed no pneumonitis or other evidence of pulmonary disease.

It is further to be observed that as far as so-called spontaneous arthritis is concerned, a chief conclusion of this work has to do with failure to reproduce arthritis as the result of certain operative procedures followed by administration of desoxycorticosterone acetate.

SUMMARY

Arthritic-like lesions were encountered in groups of rats maintained on standard laboratory rations and on grossly unbalanced diets and in animals receiving injections of massive doses of desoxycorticosterone acetate. In one group receiving massive doses of desoxycorticosterone acetate, together with a one per cent NaCl solution for drinking water, joint changes were formed in 50 per cent of young female white rats. These results are at variance with the findings of certain other workers that arthritic lesions are rarely seen in intact desoxycorticosterone-treated rats. Attempts to increase the incidence and severity of these arthritic-like lesions by exposure to cold, by thyroidectomy, adrenalectomy and gonadectomy were unsuccessful. The changes observed in the joints are those of focal areas of degeneration and ulceration in the articular cartilages.

STUDIES ON THE NEPHROTOXIC ACTION OF *DL*-SERINE IN THE RAT

III. THE INFLUENCE OF EXPERIMENTAL HYDRONEPHROSIS
MAX WACHSTEIN, M.D.
MIDDLETOWN, N. Y.

EXTENSIVE renal necrosis in the kidneys of young male rats has been shown to be caused by *DL*-serine (α -amino- β -hydroxy propionic acid).^{1,2} The protective action of various amino acids and related compounds against the damaging action of *DL*-serine^{4,5} was reported in a previous communication. *DL*-methionine and glutathione exert a considerable protective influence. This is probably not due to SH-groups since cysteine and thioglycolic acid have only small beneficial effect and 2,3-dithiopropanol (BAL) has none. *DL*-alanine, glycine, *DL*-threonine, glycolic acid, butyric acid, and pyruvic acid have a marked protective influence. *L* (+) histidine monohydrochloride and lactic acid afford appreciable protection, and *L* (+) arginine monohydrochloride and *DL*-valine, moderate protection. Some influence was seen from *L* (+) glutamic acid, while glucose, sodium acetate, and sodium chloride were without effect. It is postulated that the protective action of these substances is due to their competitive suppression of tubular reabsorption of the injurious *DL*-serine. The present report deals with the nephrotoxic effect of *DL*-serine in the presence of hydronephrosis of one kidney.

METHOD

Sixteen adult male albino rats from the Wistar strain were used. Their weight varied between 195 and 360 grams. Adult male animals were previously found to be as susceptible as young rats to the nephrotoxic action of *DL*-serine.⁶ The left ureter was ligated under sodium amytal anesthesia. *DL*-serine was injected 1, 3, 4, 6, 7, 8, 9, 12, 24, 40, 64, 88, 112, and 136 hours after ligation of the ureter. One hundred milligrams of *DL*-serine dissolved in 3 ml. of distilled water were given for each 100 grams of weight by intraperitoneal injection. The animals were sacrificed twenty-four hours later. Tissues were fixed in formalin and stained with hematoxylin-eosin. Alkaline phosphatase activity was demonstrated with Gomori's method⁷ as modified by Kabat and Furth⁸ in tissues fixed in cold acetone. The incubation time in the substrate mixture was two hours. No counterstain was used.

RESULTS

In all animals the kidneys with uninterrupted urinary flow showed extensive necrosis in the region of the cortico-medullary junction. On gross examination a small, irregularly shaped strip of grayish discoloration at the innermost portion of the cortex indicated the necrotic area (Fig. 1). The epithelium of many tubules in this area was almost completely destroyed (Fig. 2). With

Received for publication, May 15, 1947.

the help of vital staining with lithium carmine and by the maceration and dissection technique of Oliver,⁹ the kidney damage was localized to the terminal segments of the proximal convoluted tubules.⁶ There was no significant difference in the extent of renal necrosis in the obstructed as compared with the unobstructed kidney when *dl*-serine was given within three hours after the ligation of the ureter. In the kidneys that had been obstructed from four to seven hours, the extent of the necrosis was considerably decreased. In one of the experiments, only few necrotic tubules were seen in the hydronephrotic kidney of a rat injected with *dl*-serine six hours following the ligation of the ureter (Fig. 3). In all animals in which *dl*-serine was given eight or more hours

Fig. 1.—The kidneys of a male rat weighing 210 grams which was given 210 mg. *dl*-serine by intraperitoneal injection six hours after ligation of the left ureter. The animal was sacrificed twenty-four hours later. The unobstructed right kidney (top) shows an irregularly shaped strip of discoloration at the cortico-medullary junction, indicating the necrotic area. The left kidney (bottom) shows hydronephrotic dilatation without the necrotic area seen in the other kidney. Approximate magnification, $\times 2$.

following the obstruction of the ureter, a similar degree of almost complete protection in the obstructed kidney took place. Only very occasional tubules were necrotic. The kidneys in which the ureter had been ligated showed the typical gross and microscopic changes of experimental hydronephrosis increasing in intensity with the duration of the experiment.¹⁰

Phosphatase activity was normal in animals which were killed within thirty-six hours after the ureter had been ligated. Considerable decrease in phosphatase occurred in the remaining animals in which the obstruction had

lasted for a longer time. The necrotic cells in the damaged proximal convoluted tubules of the unobstructed kidney revealed phosphatase activity as previously described.⁶

COMMENT

Depression of the nephrotoxic action of mercury bichloride as early as fourteen to twenty-four hours following ligation of the ureter was described by Elbe¹¹ in 1905. Elbe's findings were later confirmed by Kosugi.¹² Frola found a similar protective influence of hydronephrosis on the damaging effect of uranium nitrate.¹³ These observations were recently extended by Willmer¹⁴ who confirmed the protective effect of experimental hydronephrosis upon the nephrotoxic action of uranium nitrate and mercury bichloride. Sucrose,¹⁵ however, as well as racemic tartaric acid and diethylene glycol produced the same amount of hydropic degeneration in the cortical tubules of the hydronephrotic and the normal kidney. In rabbits in which glomerulonephritis had been induced with duck-antirabbit serum, after the ureter in one kidney had been ligated, Reubi¹⁶ observed nearly complete protection in the obstructed kidney. In this connection the observation of Fahr¹⁷ is of interest. He found at autopsy on a 37-year-old woman severe subacute glomerulonephritic changes in one kidney, while the other kidney with hydronephrotic atrophy showed none.

As early as three hours following obstruction of one ureter there occurred appreciable diminution in toxicity, and six to seven hours following obstruction almost complete elimination of the injurious effect of *DL*-serine on the hydronephrotic kidney. The short time of obstruction necessary to modify the nephrotoxic action of *DL*-serine is more significant for this substance may cause microscopically demonstrable kidney changes within thirty minutes. These changes become extensive within the next few hours.⁶

No significant decrease in phosphatase activity is seen in the very early stage of hydronephrosis. Decrease, however, is noticeable in the hydronephrotic kidneys in the next few days and becomes progressively more pronounced. This is in full agreement with Willmer's findings.¹⁹ Lipase activity in the proximal convoluted tubules of the hydronephrotic kidney shows a similar behavior.²⁰ While, therefore, the decrease in these enzymatic activities is apparently a comparatively late sign of disturbed cellular function, there are other evidences of very early changes.

Slight general dilatation of the tubules takes place within three to six hours following ligation of the ureter.^{21, 22} Not only dilatation extending into the proximal convoluted tubules, but also flattening of epithelial cells and considerable parenchymatous and vacuolar degeneration in the cytoplasm occur within short time after ligation of the ureter.^{10, 12} In acute experiments in which the ureter of one kidney is obstructed and the urine of both kidneys is simultaneously analyzed, a decreased concentration of nitrogenous constituents and electrolytes is found.^{23, 24} The excretion of injected indigo carmine is considerably reduced as early as two to four hours following ligation of the ureter.^{23, 25}

Amino acids pass the glomerular filter and are reabsorbed in the convoluted tubules.²⁶ In view of the fact the glomerular filtration in experimental hydro-

nephrosis²⁷ is probably undisturbed for some time, an impaired passage of amino acids through the glomeruli is not likely, although not impossible.²⁸ It is reasonable to assume that early functional disturbances in the convoluted tubules are responsible for the slowing up of the reabsorption of the toxic *dl*-serine. Apparently the *dl*-serine is not concentrated in the distal portion of the proximal convoluted tubules to such an extent as to permit it to exert its destructive action.

Convoluted tubules occasionally show typical necrosis even after several days of experimental hydronephrosis. A similar phenomenon was noticed previously with mercury bichloride and uranium nitrate.^{12, 14} That even after several weeks of ligation of the ureter the convoluted tubules have not completely lost the ability to concentrate injected lithium carmine has been shown by Suzuki.²⁹

SUMMARY

In adult male rats the ureter of one kidney was ligated, and in intervals of 1 to 136 hours following the obstruction of the ureter *dl*-serine was injected. The necrotizing nephrosis induced by *dl*-serine is appreciably reduced in kidneys in which the ureter has been ligated for three to seven hours. It is almost entirely suppressed if the injurious amino acid is given eight or more hours after the ligation of the ureter. It is assumed that early disturbance of tubular reabsorption does not permit the concentration of *dl*-serine in the sensitive cells of the proximal convoluted tubules to become sufficiently great to exert its destructive action.

LABORATORY METHODS

A METHOD FOR SHOWING ANTIBACTERIAL ACTIVITY OF MINUTE QUANTITIES OF GRAMICIDIN OR PENICILLIN

E. J. FOLEY AND S. W. LEE, PH.D.
NEW BRUNSWICK, N. J.

THE test described is based on the method of Jones and Simms¹ who showed that bacteriostasis could be measured as a function of inhibition of colony size and hemolytic zones produced by Group A streptococci on blood agar plates.

Spingarn and King² used a similar procedure in studying the comparative susceptibility of Group A streptococci to penicillin.

By the use of this method we have been able to compare the activity of gramicidin and penicillin on a weight basis, and to determine the gramicidin content in tyrothricin samples. The following examples give an indication of the results obtained.

METHODS

An eighteen-hour blood broth culture of C203 (Group A) streptococcus is diluted to 10^{-5} in plain broth.

Dilutions of the drug to be tested are made in a suitable diluent, that is, penicillin in water, or tyrothricin or gramicidin in 50 per cent propylene glycol-water.

Sterile defibrinated rabbit blood (taken from rabbits which had been starved for twenty-four hours prior to heart puncture) was used. We have routinely used blood which has been at least twenty-four hours old and not more than five days old.

The tests are set up as follows: To Petri dishes (100 by 15 mm.) add:

0.5 ml. defibrinated rabbit blood

0.1 ml. 10^{-5} culture dilution

0.1 ml. drug dilution (do not mix with blood or culture until agar is added)

11.8 ml. proteose-tryptone agar melted and cooled to 45°C .

The contents of the plates must be thoroughly mixed to insure an even distribution of all components.

Various amounts of a drug in blood agar are made to give an adequate range of concentrations. This range should cover from 80 to 10 per cent inhibition of growth. Usually five plates are prepared to study one sample. Four of these contain different concentrations of the drug in blood agar, and one

(containing no drug) serves as a control. This last one gives maximum hemolytic zones around each colony.

After twenty-four hours' incubation at 37°C., the diameters of the hemolytic zones are measured with an ocular micrometer and a mechanical stage micrometer. The longest diameters of the hemolytic zones around five representative colonies are measured and averaged.

Streptococcus C203, under the conditions employed, usually gives a hemolytic zone 2.0 mm. in diameter. Smaller colonies and hemolytic zones are indications of the activity of the drug under test. To give a figure which increases with the activity, the "inhibitory activity" is expressed as

$$100-100 \frac{(\text{mm. of inhibitory zone with drug})}{(\text{mm. of inhibitory zone with no drug})}$$

Table I gives ranges of concentrations of gramicidin and crystalline penicillin per milliliter of blood agar which show differences that may be measured and plotted. The results shown are from duplicate assays on two samples of gramicidin and two batches of crystalline penicillin.

TABLE I. INHIBITION OF HEMOLYTIC ZONES OF *STREPTOCOCCUS* C203 IN BLOOD AGAR BY GRAMICIDIN AND PENICILLIN

(2)		55	35	18	

*Inhibitory activity defined as $100-100 \frac{(\text{mm. inhibitory zone with drug})}{(\text{mm. inhibitory zone with no drug})}$.

It is seen in Table I that detectable inhibition can be shown by gramicidin and penicillin when present in amounts as small as 0.8 millimicrogram per milliliter of blood agar. The results appear to be reproducible as shown by the duplicate figures. On a weight basis, penicillin appears to be more active than either of the gramicidin samples.

Tyrocidine fails to inhibit the growth of *streptococcus* C203 on blood agar plates when present in a concentration of 1 microgram of blood agar. Thus the activity shown by tyrothricin samples may be referred to as being a function of the gramicidin present.

By comparing samples of tyrothricin with a standard of known gramicidin content, it is possible to judge the gramicidin content of the unknown as greater than or less than the known standard. Table II shows such comparisons.

Sample 189 (figures show triplicate measurements) was a standard containing 20 per cent gramicidin, 80 per cent tyrocidine HCl by weight.

Sample 85-15 contained 15 per cent gramicidin and 85 per cent tyrocidine HCl by weight.

The other nine samples were from lots of tyrothricin which had been shown by the Dubos³ albumin broth test (streptococcus H69D) to contain more than 20 per cent gramicidin when compared with a known 20 per cent gramicidin control.

Table II shows reasonable reproducibility of the 20 per cent gramicidin control sample (189) in triplicate tests, and, as expected, considerably lower values are shown by the 15 per cent gramicidin sample (85-15).

TABLE II. INHIBITION OF HEMOLYTIC ZONES OF STREPTOCOCCUS C203 IN BLOOD AGAR BY TYROTHRICIN

TYROTHRICIN SAMPLE	GRAMICIDIN CONTENT (%)	INHIBITORY ACTIVITY*		
		CONCENTRATION μG DRUG PER ML. BLOOD AGAR		
		0.01 μg	0.02 μg	0.008 μg
	20	80*	50	21.5
189	20	80	46	22
	20	80	47	20
76	?		55	25
58	?		56	30
56	?		55	28
70	?		80	60
PD	?		65	45
69	?		60	40
75	?		55	30
73	?		58	28
NP	?	70	45	21
85-15	15	60	37	5

*Inhibitory activity defined as $100 - 100 \frac{(\text{mm. inhibitory zone with drug})}{(\text{mm. inhibitory zone with no drug})}$.

All of the other samples show a greater inhibitory value than the 20 per cent gramicidin control samples. Samples 70, PD, and 69 give particularly high values showing 60, 45, and 40 per cent inhibitory activity at the level of 0.008 μg per milliliter of blood-agar.

It is of interest to note that an inhibitory value of approximately 50 per cent is given by 0.02 microgram per milliliter of the standard (20 per cent gramicidin, 80 per cent tyrocidine) sample (Table II) as compared with a 50 per cent inhibitory activity by 0.004 microgram per milliliter by crystalline gramicidin (Samples 15975 and 23-19-B, Table I).

SUMMARY

A method is described by which the inhibitory effects of millimicrogram quantities of penicillin or gramicidin can be measured.

A STREAK PLATE METHOD FOR DETERMINING GROWTH CURVES

JULIA T. WELD
NEW YORK, N. Y.

WITH THE TECHNICAL ASSISTANCE OF ANNE GUNTHER

WHILE investigating the action of certain sulfur suspensions on the growth of *Staphylococcus aureus*,¹ a technique was developed which was far less laborious than the pipette dilution, pour plate method for demonstrating growth curves. By adherence to certain details of technique, remarkably reproducible graphs were obtained for the first eight hours of growth.

METHOD

Test Culture.—The first essential is to keep the inoculum within the range of the method. A three and one-half hour culture of *Staph. aureus* (Oxford strain) in bacto nutrient broth was prepared one day before each test. Two loopfuls of a 1:20,000 dilution were spread separately on two halves of an agar plate to estimate the population. The culture was then left overnight in the icebox.

Agar.—Twelve to fifteen cubic centimeters of bacto nutrient agar (1.5 per cent agar) were poured into Petri plates which were stored three to four days at 37° C. to dry. This was necessary to avoid condensation on the surface of the agar which interferes with accurate bacterial counts.

Loop.—A standard loop of nichrome wire, which when filled held approximately 0.002 c.c. of broth, was employed. In making subcultures the tube containing the test material was held in a slightly slanted position and only the loop immersed, taking care to pick up the maximum amount of fluid. Recently Calkins² has shown that under specified conditions the quantity of fluid taken up by a loop is remarkably constant.

Spreading a Loopful of Fluid.—The dry agar plates were ruled horizontally with a glass pencil, the size of the area between the lines being proportional to the expected bacterial count. (When large counts are expected, a whole plate is used for one preparation.) Then one loopful from each test preparation was spread evenly over the entire surface of the agar marked out for it, care being taken to avoid cutting into the agar with the loop. It is, of course, important not to leave even tiny droplets of test fluid unspread.

The Bacterial Count.—The colonies were counted after eighteen to twenty-four hours' growth at 37° C. The figures obtained were multiplied by a factor of 500 to convert them to bacteria per cubic centimeter, since one loopful held 0.002 c.c. of culture. It is obvious that negative cultures might be obtained from cultures that actually contain a few organisms per cubic centimeter.

When an entire plate was used, at least 200 individual colonies (representing 100,000 organisms per cubic centimeter) were counted. When properly inoculated, none of the colonies run into one another (see Plate I).

In the first eight hours of growth, the period of interest in our present study, the number of organisms in one loop was rarely more than 200. Therefore, the graphs represent the actual number of organisms in undiluted cultures, calculated to 1 c.c. volume. When the counts were higher than 200 colonies per plate, rough estimates were made and recorded, such as 1 plus for 200 to 400 colonies; 2 plus for 400 to 600 colonies; 3 plus for 600 to 800 colonies; and 4 plus for over 800 colonies.

From the Departments of Pathology and Dermatology, College of Physicians and Surgeons, Columbia University.

Received for publication, May 31, 1947.

The control tube was usually slightly cloudy after four hours' growth, and always definitely cloudy after six hours. In such preparations the count was always in the millions and, therefore, out of the range of this technique.

One possible source of error was that a loopful of test fluid, especially from the higher concentrations of an antibacterial agent, might have carried over sufficient material to inhibit growth. To explore this possibility, in several of our experiments one loop was spread over agar as usual, and a second loop from the same tube was mixed with melted and cooled agar for pour plates. We found that the two sets of counts were essentially alike and therefore concluded that the possibility of this error in our bacterial counts was no greater than the possibility of error with the pour plate method.

Plate I.*—Antibacterial effect of penicillin upon the growth of *Staph. aureus*. Streak cultures of test mixture dilutions made on agar after two hours' incubation at 37° C.

READING DOWNWARD	COLONY COUNT	CALCULATED NUMBER OF ORGANISMS/C.C.
1. Penicillin content 0.1 u./c.c.	0	0
2. Penicillin content 0.075 u./c.c.	5	2,500
3. Penicillin content 0.05 u./c.c.	14	7,000
4. Penicillin content 0.025 u./c.c.	130	65,000
5. Penicillin content 0.01 u./c.c.	190	95,000

The initial number of organisms per c.c. was 27,500.

The control test after two hours' incubation at 37° C. contained over 100,000 organisms per cubic centimeter.

TEST PROCEDURE

The number of organisms in the test culture prepared the previous day was estimated from the preliminary plates of that day, and this culture was

*Actual size. Photographed by Mrs. Miriam Wallace.

diluted on the day of the test so as to contain 100,000 to 600,000 cells per cubic centimeter. Appropriate dilutions of the antibacterial substance were distributed in tubes in 1 c.c. amounts, and 0.05 c.c. of the test culture was added to each tube. Two loopfuls of the control tube were at once spread out separately on two halves of an agar plate to determine the initial count. The test preparations were then placed in a water bath at 37° C. At one-hour, two-hour, or longer intervals, one loopful from each was spread over the surface of the agar allotted to it. Six antibacterial agents, each in eight dilutions, were easily tested at one-hour or two-hour intervals by one worker.

Where the antibacterial agent was dissolved in a solvent such as alcohol or carbowax,^{1, 3} controls were made to determine whether the solvent itself affected the bacteria.

Fig. 1.—Antibacterial action of phenol for *Staph. aureus*.

RESULTS

Figs. 1 to 11* show the growth curves of *Staph. aureus* in the presence of the following antibacterial substances: phenol, streptothricin, streptomycin, clavacin, penicillin, protoanemonin, Manganese protoporphyrin, alcohol-sulfur, carbowax-sulfur, sulfanilamide, and pentathionic acid. Figs. 1. to 11 show single experiments, all of which have been repeated at least once with essentially similar growth curves.

Fig. 2.—Antibacterial action of streptothricin for *Staph. aureus* (units per cubic centimeter).

Protoanemonin is an antibacterial agent, described by Seegal and Holden⁴ and by Baer, Holden, and Seegal,⁵ active not only against the growth of certain gram-positive and gram-negative bacteria, but also against *Cryptococcus hominis*

*We are indebted to Miss Natalie Pearlstein for the preparation of Figs. 1 to 11.

and *Candida albicans*. The preparation used was a distillate of the stems, leaves, and blossoms of *Anemone pulsatilla*. Mn. protoporphyrin has been shown by Granick and Gilder⁶ to inhibit a variety of organisms including *Staph. aureus* and the acid-fast bacilli in concentrations of 0.5 to 3 gamma per cubic centimeter. The sulfur preparations were suspensions of sulfur in alcohol

Fig. 3.—Antibacterial action of streptomycin for *Staph. aureus* (units per cubic centimeter).

(alcohol-sulfur) and in carbowax (carbowax-sulfur) which the authors have found inhibitory for *Staph. aureus* in preparations containing only 0.1 to 0.3 gamma of sulfur per cubic centimeter and for certain fungi in concentrations as low as 0.4 gamma. Pentathionic acid* was tested because it was suspected

*We are indebted to Dr. W. A. Knapp of the General Chemical Co., New York, N. Y., for making this material available to us. The $H_2S_2O_8$ prepared according to the Liming method was an 8 per cent solution of $H_2S_2O_8$ containing tetra and trithionic acids but no thiosulfates.

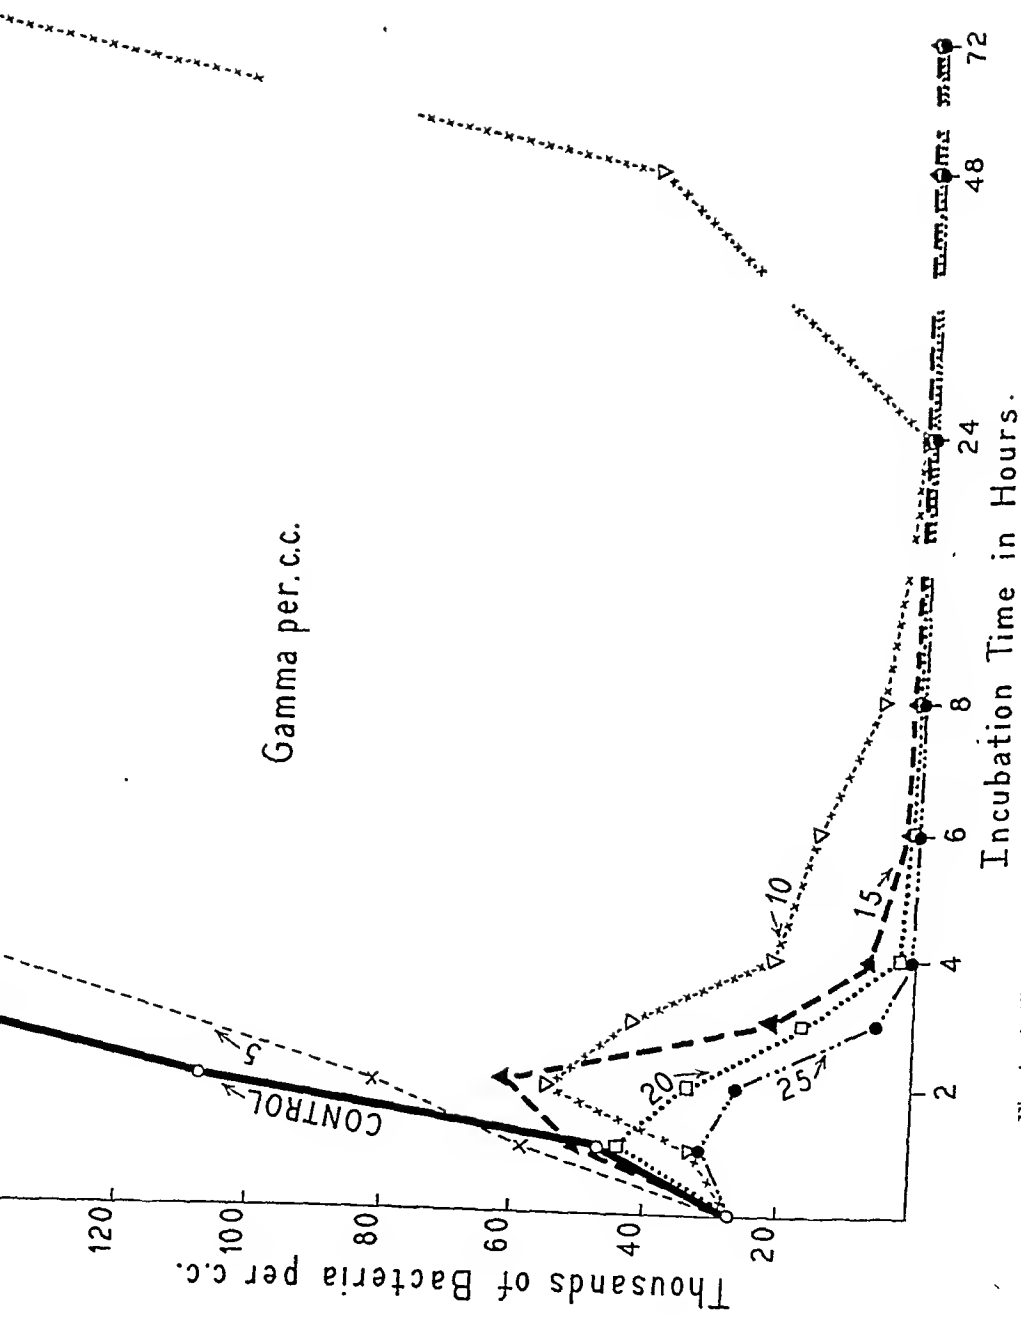

Fig. 4. — Gamma per.c.c. vs. Incubation Time in Hours.

that if present in the sulfur preparations it might explain their extraordinary activity.

The curves showed at once important differences in the effects of these antibacterial agents in the ranges of concentration in which they were active. The more important differences are summarized in Table I. Even more interesting were the patterns of these curves obtained in the first eight hours of

Fig. 5.—Antibacterial action of penicillin for *Staph. aureus* (units per cubic centimeter).

growth. These differed in each instance and seemed characteristic for the substances studied. The following phenomena were noted:

1. *Early Bactericidal Effect*.—The statement that certain agents were bactericidal is made with the same reservations necessary in testing for bactericidal effect by most methods in current use. It was not proved that the effect was

TABLE I. COMPARISON OF BACTERICIDAL AND BACTERIOSTATIC EFFECTS OF VARIOUS ANTIBACTERIAL AGENTS

1 ANTIBACTERIAL AGENT	2 MINIMUM BACTERICIDAL DOSE	3 BACTERICIDAL EFFECT IN HOURS	4 MAXIMUM NONINHIBIT- ING DOSE†	5 RATIO $\frac{\text{COLUMN 2}}{\text{COLUMN 4}}$

*No growth from one loop (0.002 c.c.) inoculum.

†No bactericidal effect in largest amounts tested in eight hours.

‡Maximum dose of antibacterial agent giving curve approximately like that of control.
Doses listed delayed growth slightly. See Fig. 2, 0.5 unit curve; Fig. 3, 0.005 unit curve; Fig. 4, 5 µg curve, etc.

Fig. 6.—Antibacterial action of protoanemonin.

Fig. 7.—Antibacterial action of Mn. protoporphyrin for *Staph. aureus* (gamma per cubic centimeter).

irreversible, nor was it proved that subculture of a larger sample might not have shown a few surviving cells.

It was evident, however, that the effect of phenol was purely bactericidal in the usually accepted sense. High concentrations of streptothricin, streptomycin,* and penicillin also appeared bactericidal within two hours. A slower

Fig. 3.—Antibacterial action of alcohol solution of sulfur (alcohol-sulfur) for *Staph. aureus*.

bactericidal effect is shown by clavacin and protoanemonin in six and eight hours, respectively. The other three antibacterial agents (Mn, protoporphyrin, alcohol-sulfur, and carbowax-sulfur), even in the highest concentrations used, showed no bactericidal effect during the first eight-hour period of growth.

*The 0.2 unit curve which gave negative cultures at one, two, four, six, eight, twenty-four, and forty-eight hours is omitted from Fig. 3.

STREAK PLATE METHOD FOR GROWTH CURVES

Sulfanilamide also showed no bactericidal effect, but this may have been due to its insolubility in sufficiently high concentration. Adequate test of pentathionic acid could not be made because high concentrations were too acid to permit growth of the staphylococcus.

Fig. 9.—Antibacterial action of carbowax solution of sulfur (carbowax-sulfur) for *Staph. aureus*.

2. *The Phase of Early Growth Followed by Inhibition.*—This occurs with intermediate concentrations of several of the antibacterial agents tested. It is seen at approximately two hours with streptothricin. A more prolonged growth phase with a peak of growth at six hours is shown by protoanemonin and sulfanilamide. Mn. protoporphyrin differs from streptothricin and protoanemonin in that it permitted rapid early growth with peaks at four to eight hours. The other antibacterial agents tested show no definite early phase of growth.

3. *Bacteriostatic Effect.*—All agents tested showed a zone in which the cocci were inhibited for a period but began active growth within eight hours. With phenol the period lasted only two hours in a narrow zone of concentration. With protoanemonin, clavaein, and penicillin the range of concentration showing only inhibition was also narrow. It was somewhat wider in streptothricin, streptomycin, and Mn. protoporphyrin. The curves for sulfanilamide also

Fig. 10.—Antibacterial action of sulfanilamide for *Staph. aureus*.

showed inhibition only in a narrow zone, but this may have been due to the presence of sulfonamide antagonists in the medium which counteracted its effect except in high concentration. The low pH of strong solutions of pentathionie acid also prevented determination of its range of activity.

With the sulfur suspensions, inhibition seemed of a different order. In these there was an enormous range of concentrations in which the organisms were held at about the inoculation level for from four to eight hours, only to grow out freely at a later period. Tubes with higher concentrations in which the organisms were inhibited for twenty-four hours or longer appeared sterile on transfer. It seemed more probable that this was due to senescence of the inhibited organisms rather than to direct bactericidal effect.^s

Fig. 11.—Antibacterial action of pentathionic acid for *Staph. aureus* (gamma per cubic centimeter).

4. *The Renewal of Growth Phenomenon.*—This was seen after eight to twenty-four hours' growth, with intermediate concentrations of several antibacterial substances after the organisms had practically disappeared from the cultures and appeared to be dying out. This was probably due to the presence

of a small number of resistant organisms in the test culture.⁹⁻¹¹ This phenomenon is most apparent with streptothricin and streptomycin and, to a less extent, with clavacin and possibly with *Mn. protoporphyrin*. It was not seen in the sulfur preparations or with sulfanilamide. In concentrations of these latter agents, which inhibited the staphylococci for eight hours, the organisms failed to grow out after longer exposure.

Table I demonstrates that the substances tested may be separated roughly into two groups:

1. Antibacterial agents which are bactericidal in eight hours or less. In this group the minimum bactericidal dose is only 40 or less times the maximum noninhibiting dose. The range of dilutions which gives inhibition without bactericidal effect is small.

2. Antibacterial agents which are merely bacteriostatic in eight hours. This group gives only bacteriostasis in doses as high as 80 to 8,000 times the maximum noninhibiting dose. The range of dilutions which gives inhibition is large.

SUMMARY

A simple streak plate method for demonstrating growth curves of *Staph. aureus* under the influence of antibacterial agents is described.

Graphs are presented showing the effect of the following antibacterial agents:

Phenol: A rapidly bactericidal substance which kills the organisms in a concentration only slightly higher than one which has even no inhibiting effect.

Streptothricin, Streptomycin, Clavacin, Penicillin and Protoanemonin: Antibacterial agents which kill the organisms in eight hours or less in concentrations not more than 40 times the noninhibiting doses.

Mn. protoporphyrin and Suspensions of Sulfur in Alcohol (Alcohol-Sulfur) and in Carbowax (Carbowax-Sulfur): Purely bacteriostatic preparations which fail to kill the organisms in eight hours in the highest concentrations tested but inhibit growth completely in minute fractions of such amounts.

FLUID THIOGLYCOLLATE MEDIUM

ITS USE FOR TESTING THE STERILITY OF SURGICAL CATGUT SUTURES

RALPH OAKLEY CLOCK, M.D.

BROOKLYN, N. Y.

BREWER,¹ in 1940, announced his fluid thioglycollate medium for the cultivation of anaerobes and stated that it also would support growth of aerobes. In his table, he showed that *Clostridium novyi* would grow satisfactorily up to a month after sterilization of the culture medium, but he did not mention the size of the inoculum used. He stated in his paper: "The sodium thioglycollate combines with and inactivates most of the mercurials used as preservatives, and one is much more likely to obtain growth from contaminated biologicals which are preserved with one of these highly bacteriostatic compounds."

McClung⁴ reported that Brewer's thioglycollate medium compares favorably with complex meat infusions in its ability to initiate growth from small numbers of cells. For his tests, eleven different species of anaerobes including *Cl. novyi* were used.

Nungester, Hood, and Warren⁶ conducted experiments to determine whether the addition of sodium thioglycollate to culture medium used in testing disinfectants by an *in vitro* method would give results similar to those obtained by the "infection-prevention" method. They experimented with six mercurial compounds and found the percentage of positive growths was much greater when a culture medium containing thioglycollate was used. They concluded: "Sodium thioglycollate added to media for testing disinfectants *in vitro* apparently neutralized the bacteriostatic effect of the mercurial compounds tested and thus indicated the inadequacy of these substances as germicides."

As a result of Brewer's findings, that the addition of sodium thioglycollate to culture medium inhibits the bacteriostatic action of mercurials, the National Institute of Health⁵ specified a formula for fluid thioglycollate medium which it recommends for use in testing the sterility of biologic products. This culture medium* is a modification of the original Brewer formula.

It has been suggested that fluid thioglycollate medium might be used effectively to test the sterility of all products that are preserved or impregnated with mercurial compounds. Such a procedure would utilize the fluid thioglycollate medium for testing the sterility of surgical catgut sutures instead of the culture media officially prescribed by the *United States Pharmacopoeia XII*.

PURPOSE OF INVESTIGATION

The purpose of this investigation was twofold: (1) to determine the comparative growth-promoting properties of the National Institute of Health formula for fluid thioglycollate medium with those of the Novy culture medium which is specified in the U. S. P. XII as the official anaerobic medium, and (2)

Received for publication, June 1, 1947.

*Prepared by the Difco Laboratories, Incorporated, Detroit, Mich.

to determine the efficiency of the fluid thioglycollate medium for testing the sterility of surgical catgut sutures *without* employing the inactivating fluids which constitute part of the U. S. P. XII Sterility Tests for Solids.

MATERIALS AND METHODS

The culture media comprised (1) bacto-fluid thioglycollate medium and (2) the U. S. P. XII medium prepared for aerobiosis and that prepared for anaerobiosis. The fluid thioglycollate medium was incubated without seal, while tubes of the U. S. P. XII anaerobic medium were sealed with a mixture of equal parts of petroleum jelly and paraffin. The final pH of the fluid thioglycollate medium was adjusted to 7.1 as recommended by Pittman,⁷ while that of the U. S. P. XII media was adjusted to 7.4 as specified in the U. S. P. XII.

A series of experiments was conducted to determine the growth-promoting properties of the fluid thioglycollate medium and of the U. S. P. XII anaerobic medium, using *Cl. novyi* as the test organism in decimal dilutions. In the official Sterility Tests for Solids, the U. S. P. XII specifies⁸ *Cl. novyi* for the control organism to determine the growth-promoting properties of the culture medium.

Another series of experiments involved the testing for sterility of catgut sutures artificially infected with a sporulating culture of *Clostridium sporogenes* and *Bacillus subtilis*, and impregnated with mercuric iodide to the amount of 1 per cent in some of the sutures and 3.5 per cent in others.

EXPERIMENTS TO DETERMINE GROWTH-PROMOTING PROPERTIES

Several tubes of the fluid thioglycollate medium and of the U. S. P. XII anaerobic medium were inoculated with 1 c.e. of decimal dilutions (from 10^{-1} to 10^{-10}) of a forty-eight hour broth culture of *Cl. novyi*. Typical protocols are shown in Table I. This experiment was repeated several times and the results were similar to those shown in the table.

Discussion of Results.—

1. *Fluid Thioglycollate Medium*: After twenty-four hours gas formed in the first dilution, and a very light bacterial growth occurred from an inoculum of 0.000001 c.e. (10^{-6}).

After forty-eight hours gas formed in the first five tubes.

After five days maximum degree of growth (4 plus) occurred from an inoculum of 0.00001 c.e. (10^{-5}), gas formed from an inoculum of 0.000001 c.e. (10^{-6}), and a very light bacterial growth was present in the tube containing an inoculum of 0.00000001 c.e. (10^{-8}).

2. *U. S. P. XII Anaerobic Medium*: After twenty-four hours, a very light bacterial growth was present in the tube containing an inoculum of 0.00001 c.e. (10^{-5}), but gas did not form in any of the tubes.

After forty-eight hours gas formed in the first four tubes.

After five days maximum degree of growth (4 plus) occurred from an inoculum of 0.001 c.e. (10^{-3}), gas formed from an inoculum of 0.00001 c.e. (10^{-5}), and a light bacterial growth occurred from an inoculum of 0.000001 c.e. (10^{-6}).

TABLE I

MEDIUM	INCUBATION PERIOD	DECIMAL DILUTIONS									
		10-1	10-2	10-3	10-4	10-5	10-6	10-7	10-8	10-9	10-10
Bacto-fluid thioglycollate medium	24 hr.	4+ gas	3+	3+	2+	2+	+	0	0	0	0
	48 hr.	4+ gas	4+ gas	4+ gas	3+ gas	3+ gas	2+	+	0	0	0
	5 days	4+ gas	4+ gas	4+ gas	4+ gas	4+ gas	3+	2+	+	0	0
U. S. P. medium for anaerobiosis	24 hr.	4+	3+	2+	+	+	0	0	0	0	0
	48 hr.	4+ gas	4+ gas	3+ gas	3+ gas	2+	+	0	0	0	0
	5 days	4+ gas	4+ gas	4+ gas	3+ gas	3+ gas	2+	0	0	0	0

The degree of bacterial growth is indicated by plus signs: very light cloud, 1 plus; light cloud, 2 plus; heavy cloud, 3 plus; and very heavy cloud, 4 plus. Absence of growth is indicated by 0.

Decimal dilutions of a forty-one and the comparative growth-promoting P. XII anaerobic medium. In the tubes of the U. S. P. anaerobic medium, bacterial growth was present on the fifth day in the tubes of bacto-fluid thioglycollate medium as far out as the eighth dilution in contrast to the sixth dilution in the tubes of the U. S. P. anaerobic medium.

These results indicate that the fluid thioglycollate medium is superior to the U. S. P. XII anaerobic medium for supporting the growth of anaerobic bacteria, such as *Cl. novyi*. This superiority is shown (1) after twenty-four hours' incubation, by gas formation in the first dilution and by bacterial growth out as far as the sixth dilution; (2) after forty-eight hours' incubation, by the maximum degree of growth occurring in one higher dilution and by bacterial growth being present in one higher dilution; and (3) after five days' incubation, by gas formation in one higher dilution, by the maximum degree of bacterial growth occurring in two dilutions higher, and by bacterial growth being present out as far as the eighth dilution in contrast to the sixth dilution.

EXPERIMENTS ON INACTIVATION OF MERCURIALS

To determine the extent of the combining and inactivating properties of thioglycollic acid (contained in the fluid thioglycollate medium) for mercuric, a series of experiments was carried out in which artificially infected catgut sutures containing 1 per cent mercuric iodide (Lot 1754) and some containing 3.5 per cent mercuric iodide (Lot 1755) were tested for sterility. The sutures were infected with a sporulating culture of *Clostridium sporogenes* and *Bacillus subtilis*. For controls, sutures artificially infected with the sporulating culture but not impregnated with any chemical compound (Lot 1753) were used.

Comparative tests were made by placing some of each of the three different lots of sutures directly into tubes containing 40 c.c. fluid thioglycollate medium and incubating at 37° C.; other sutures of each of the three lots were tested in accordance with the sterility technique prescribed by the U. S. P. XII. This latter technique consisted of incubating the sutures first in tubes of 40 c.c. distilled water, then in tubes containing the inactivating fluid of 1 per cent

sodium thiosulfate and 1 per cent sodium carbonate; on the third day the sutures were transferred to tubes of distilled water and incubated twenty-four hours; and on the fourth day the sutures were transferred to tubes of beef broth prepared for aerobiosis and incubated, or transferred to tubes of gelatin beef broth prepared for anaerobiosis and sealed with a mixture of petroleum jelly and paraffin and then incubated. Results of these comparative tests are shown in Tables II and III.

TABLE II

LOT	BACTO-FLUID THIOGLYCOLLATE MEDIUM	
	AEROBIC RESULTS	ANAEROBIC RESULTS
1753 (Control)	24-hour growth, gram-positive rods	24-hour growth; gram positive rods with subterminal spores; gas formation
1754 (Containing 1% mercury)	24-hour growth, gram-positive rods	24 hour growth; gram positive rods with subterminal spores; gas formation
1755 (Containing 3.5% mercury)	24 hour growth, gram-positive rods	24 hour growth; gram-positive rods with subterminal spores; gas formation

The inactivating properties of bacto-fluid thioglycollate medium for mercury were determined by sterility tests of eight sutures artificially infected with a sporulating culture. Some sutures contained 1 per cent mercury, while others with 1.5 per cent mercury. For controls, sutures artificially infected but not with mercury were used. These tests show that the thioglycolic acid in the bacto-fluid thioglycollate medium combines with and inactivates 1 per cent mercury and 3.5 per cent mercury, so that twenty-four hour growths occurred in all tubes and corresponded to the growths in the control tubes.

The results given in Table II indicate that the thioglycollic acid in the fluid thioglycollate medium combines with and inactivates the 1 per cent of mercury and the 3.5 per cent of mercury, as shown by the aerobic and anaerobic bacterial growths which occurred in Lots 1754 and 1755 and which checked with the control Lot 1753.

Table III shows the results of using the U. S. P. XII technique. It will be noted that the mercurial salts present in the sutures to the amount of 1 per cent combine with the sodium thiosulfate of the inactivating fluid to form a double salt which is soluble in water, as shown by the aerobic and anaerobic bacterial growths in Lot 1754. However, the amount of mercury in sutures of Lot 1755 is so great (3.5 per cent) that all of it will not combine with the sodium thiosulfate of the inactivating fluid, and enough mercury is still present in the sutures to exert a bacteriostatic effect and prevent bacterial growth.

TABLE III

LOT	U.S.P. AEROBIC MEDIUM	U.S.P. ANAEROBIC MEDIUM
	AEROBIC RESULTS	ANAEROBIC RESULTS
1753 (Control)	24 hour growth, gram positive rods	24 hour growth; gram positive rods with subterminal spores; gas formation
1754 (Containing 1% mercury)	24 hour growth, gram-positive rods	24 hour growth; gram-positive rods with subterminal spores; gas formation
1755 (Containing 3.5% mercury)	No growth after 15 days' incubation	No growth after 15 days' incubation

Experiments were made to determine the inactivating properties for mercury of the standard inactivating fluid of 1 per cent sodium thiosulfate and 1 per cent sodium carbonate prescribed by the U. S. P. XII. Catgut sutures artificially infected and containing 1 per cent mercury and some containing 3.5 per cent mercury were tested for sterility by the U. S. P. XII technique. For controls, sutures artificially infected but not impregnated with mercury were used. These tests show that the standard inactivating fluid combines with and inactivates 1 per cent mercury (as shown by twenty-four hour growths in Lot 1754), but that it is not capable of combining with and inactivating 3.5 per cent mercury (as shown by the absence of growth in Lot 1755).

In my bacteriologic investigations of chemical sterilization of surgical catgut sutures, I devised² an inactivating fluid of 10 per cent sodium thiosulfate for effectively combining with and inactivating mercurial compounds if present in amounts greater than 2 per cent. I recommended³ the use of this 10 per cent sodium thiosulfate solution as an inactivating fluid whenever catgut sutures are found upon chemical analyses to contain more than 2 per cent of mercury. The U. S. P. XII adopted⁸ this procedure as part of the official Sterility Tests for Solids.

Accordingly, additional sutures from Lot 1755 were tested by the U. S. P. XII technique in which the 10 per cent sodium thiosulfate inactivating fluid was used, with results shown in Table IV.

TABLE IV

LOT	U.S.P. AEROBIC MEDIUM	U.S.P. ANAEROBIC MEDIUM
	AEROBIC RESULTS	ANAEROBIC RESULTS
1753 (Control)	Growth in 24 hours, gram-positive rods	Growth in 24 hours: gram-positive rods with subterminal spores; gas formation
1755 (Containing 3.5% mercury)	Growth in 24 hours, gram-positive rods	Growth in 24 hours: gram-positive rods with subterminal spores; gas formation

Experiments were made to determine the inactivating properties of the special inactivating fluid of 10 per cent sodium thiosulfate prescribed in the U. S. P. XII sterility technique when large amounts of mercury are present in sutures. Catgut sutures artificially infected with a sporulating culture and containing 3.5 per cent mercury were tested for sterility. Sutures artificially infected but not impregnated with mercury were used for controls. These tests show that the special inactivating fluid of 10 per cent sodium thiosulfate combines with and inactivates 3.5 per cent mercury, so that in all tubes of Lot 1755 growths occurred in twenty-four hours, which corresponded to growths in the controls.

These results demonstrate that the special inactivating fluid of 10 per cent sodium thiosulfate is required in connection with the U. S. P. XII technique in order to detect the presence of living bacteria in catgut sutures which are heavily impregnated with mercurial salts. This special inactivating fluid eliminates all bacteriostatic action of the mercury, thereby allowing the bacteria in the catgut to germinate in the culture medium.

Discussion of Results.—This series of experiments to determine the inactivation of mercurials demonstrates in a convincing manner that the fluid thioglycollate medium is superior to the U. S. P. XII culture media for testing the sterility of surgical catgut sutures. It simplifies the technique because it may be used *without* the inactivating fluids specified in the U. S. P. XII for the inactivation of mercurial salts. The thioglycollic acid contained in the fluid thioglycollate medium combines with the mercury and thereby eliminates all bacteriostatic action of mercurial salts when present in catgut sutures in amounts as great as 3.5 per cent.

CONCLUSIONS

The experiments herein described demonstrate that bacto-fluid thioglycollate medium is superior, in the following respects, to the U. S. P. XII culture media for testing the sterility of surgical catgut sutures:

1. A smaller inoculum supports the growth of anaerobic bacteria, such as *C. novyi*.
2. Gas forms earlier, and maximum bacterial growth occurs from a much smaller inoculum.

3. No seal is required for anaerobiosis, since the sodium salt of thioglycollic acid lowers the oxidation reduction potential which is maintained for a considerable period of time by the agar in the medium.

4. Preliminary incubation in distilled water and inactivating fluids, for the purpose of removing bacteriostatic mercurial salts with which the sutures may be impregnated, is not required.

5. The sodium salt of thioglycollic acid in the culture medium effectively neutralizes the bacteriostatic action of mercurial compounds when present in catgut sutures in amounts up to 3.5 per cent.

Since these experiments were completed, the Committee of Revision of the United States Pharmacopoeia adopted the National Institute of Health formula for fluid thioglycollate medium for use in Sterility Tests for Liquids and Solids, and it will become the official sterility test medium in the U. S. P. XIII.

DETERMINATION OF INULIN IN PLASMA AND URINE

N. HERZ AND B. SHAPIRO

JERUSALEM, PALESTINE

THE use of inulin in measuring glomerular filtration has stimulated the development of a great number of methods for the estimation of this substance in plasma and urine. Among the reagents used, diphenylamine appears to yield the greatest color density per milligram of inulin present. However, even employing this reagent in Harrison's² modification of the method of Alving, Rubin, and Miller, we found that the color produced by low concentrations of inulin (4 to 20 mg. per cent) proved to be too feeble to permit exact readings in the Pulfrich photometer. Since it is known that the color intensity obtained with diphenylamine is greatly reduced in the presence of water, we attempted to find a method for precipitating inulin from the plasma filtrates and for subsequently carrying out the estimation with the dried precipitate. Such a method would have an additional advantage in that larger aliquots could be analyzed than have been possible with current methods.

In preliminary experiments it was found that inulin can be quantitatively precipitated from solution by treatment with calcium hydroxide. No sugar can be detected in the supernatant fluid, nor is any sugar eluted by subsequent washing of the precipitate with alkaline water or with alcohol. On addition of the strongly acid diphenylamine reagent, calcium hydroxide is easily dissolved, setting free the precipitated inulin for hydrolysis and color production.

The following method was evolved for the determination of inulin in blood and urine as part of the measurement of inulin clearance in man.

METHOD

Solutions.—

Zinc sulfate solution 10 per cent.

Sodium hydroxide solution N/2.

Calcium chloride solution 2N.

Sodium hydroxide solution 2N.

Saturated solution of calcium hydroxide in water.

Saturated solution of calcium hydroxide in alcohol.

Diphenylamine reagent. 3 Gm. diphenylamine dissolved in 100 ml. glacial acetic acid. Add 60 ml. concentrated hydrochloric acid. Store in amber bottle in a cold place.

Inulin stock solution. 100 mg. inulin in 100 ml. water containing 1 drop of N/10 sodium hydroxide. This solution keeps for two weeks in a cold place.

From the Chemical and Physiological Laboratory, Rothschild Hadassah University Hospital, and the Laboratory for Pathological Physiology, The Hebrew University.

Received for publication, May 29, 1947.

²Harrison, H. E.: A Modification of the Diphenylamine Method for Determination of Inulin, *Proc. Soc. Exper. Biol. & Med.* 49: 111, 1942.

Working standard. Freshly prepared from the stock solution by diluting 2 to 100 ml. with water.

Procedure.—Measure 0.2 to 0.5 ml. of plasma or serum containing 10 to 100 μ g of inulin into a centrifuge tube. Make up to 9 ml. with water, add 0.5 ml. zinc sulfate solution, and mix. Add 0.5 ml. of N/2 sodium hydroxide solution, mix, centrifuge, and filter. Measure 5 ml. of the clear filtrate into a centrifuge tube and add 0.5 ml. calcium chloride solution and 0.5 ml. 2N sodium hydroxide solution. Heat in a boiling water bath for five minutes. Centrifuge sharply for five minutes. Decant the supernatant fluid. Wash the precipitate with 5 ml. of the aqueous solution of calcium hydroxide, using a small glass rod for each tube in order to break up the larger clumps. Put the rods aside for further use with their respective tubes. Centrifuge the suspension sharply, decant, and wash with alcohol-calcium hydroxide as described. After decantation drive off the remaining alcohol by immersing the tubes in a boiling water bath for five minutes. Return the rods to their tubes. Add 5 ml. of diphenylamine reagent, stir well, and heat in a boiling water bath for exactly thirty minutes. Cool in cold water. Read in a photometer with a filter transmitting at 610 millimicrons.

Each run includes one plasma blank from the patient's blood before the injection, and two standards, prepared by adding 0.5 ml. of the blank plasma to 2 ml. and 4 ml. of the standard inulin solution, making up to 9 ml., and proceeding as described.

Urine is diluted 500- to 1,000-fold. To 5 ml. of the diluted urine add 0.5 ml. of calcium chloride solution, and proceed as with the blood filtrates. A blank value is determined from the patient's urine before the test.

Calculation.—The extinction values obtained with the two standards included in the series give the factors needed for calculation of both plasma concentration and urinary excretion.

DISCUSSION OF METHOD

Color Intensity.—With this method, 10 μ g of inulin in the final solution gave an extinction of 0.2 with a 10 mm. cell. This value was practically constant. We do not, however, propose to dispense with the inclusion of standards in each run, since changes might occur in heating conditions or in various reagent batches which would otherwise remain undetected.

Our method achieves color intensities five times as strong as those obtained with Harrison's method (Table I). This is accounted for by our use of 5 ml. of

blood filtrate instead of 2 ml. and by the exclusion of water, giving an additional reduplication of color.

Precipitation of Inulin.—The amount of precipitant used was found to allow for quantities of inulin in plasma filtrates up to 100 micrograms. Attempts to dispense with the boiling for precipitation have yielded erratic results. Heat seems to be necessary to insure a stable relation between inulin and calcium hydroxide which will withstand subsequent washing.

Blanks.—The diphenylamine reagent develops a color with ageing and should be frequently prepared in small quantities. We found the urine blank values to be no higher than those of the reagent blank with water. A water blank may, therefore, be substituted for the urine blank proposed if no sugar or other abnormal constituents are present which produce color with the reagent. Serum blank values were equivalent to about 4 to 5 mg. per cent inulin. The same extinction was obtained by treating a solution of 100 mg. per cent glucose in water as described for plasma. It is thus mainly glucose which is responsible for the serum blank value. The proportion of 1:25 in color produced by glucose and inulin, respectively, would require a fluctuation in blood sugar of 25 mg. per cent in order to change the apparent inulin content by 1 mg. per cent. We consider ourselves, therefore, justified in dispensing with yeast treatment, except under very special experimental conditions.

Recovery Experiments.—Recovery experiments are presented in Table II.

Application of the Method for Inulin Clearance Tests.—With the described method for inulin determination, we found it entirely sufficient to inject only 1.5 or 2 Gm. intravenously instead of the usual 10 grams. This dose gives an initial serum level of 12 to 15 mg. per cent with sufficient time for several clearance periods before the concentration has fallen too low for determination. This should make inulin clearance studies more attractive to clinicians, who have been reluctant to undertake them because of the danger of pyrexial reactions. The higher color production makes clearance studies feasible even in small laboratory animals by reducing the quantity of plasma required for analysis.

SUMMARY

A method has been developed for the estimation of inulin in blood plasma and in urine. Inulin is precipitated with calcium hydroxide and the color elicited with the dry precipitate with diphenylamine. This increases greatly the color intensity obtained.

The method permits the reduction of the inulin dose injected for clearance tests in human beings and makes clearance tests feasible in small laboratory animals.

The authors are greatly indebted to Prof. E. Wertheimer for his encouragement and constant interest.

CHROMATOGRAPHIC SEPARATION OF CHOLESTEROL AND CHOLESTEROL ESTERS IN BLOOD

WALTER C. HESS, PH.D.
WASHINGTON, D. C.

THE methods commonly used for the determination of free cholesterol in blood depend upon its precipitation with digitonin followed by the development of color directly upon the digitonide, usually with the Liebermann-Burchard procedure.¹⁻³ The estimation of cholesterol esters, which are not precipitated by digitonin, should be done after saponification because, as has been repeatedly shown, the esters give more color in the Liebermann-Burchard method than does free cholesterol.⁴⁻⁸ In the estimation of both free and ester cholesterol these two methods are combined.^{2, 3} For complete precipitation of the cholesterol digitonide twenty-four hours are required, although Schoenheimer and Sperry² state that satisfactory results can be obtained with only one-hour standing. A method which would eliminate the costly and time-consuming digitonin precipitation is to be desired.

Trappe⁹ used aluminum oxide to adsorb various lipids from petroleum ether solution and separated cholesterol stearate from free cholesterol by first eluting with trichlorethane to remove the ester and then with absolute ethyl alcohol to remove the cholesterol. He used large amounts of material, 71.2 mg. of cholesterol stearate and 72.2 mg. of cholesterol, and recovered 99.3 per cent of the stearate despite the fact that there was some saponification of the ester. A satisfactory method for blood analysis would require the separation and determination of much smaller quantities of cholesterol ester and free cholesterol. Subsequently Trappe^{10, 11} described a method for the determination of both free and ester cholesterol in whole blood based, in part, upon these experiments. His procedure involved the use of both silica gel and aluminum oxide; however, no values for either plasma or serum were given.

Chromatographic procedures have been used in our laboratory for the separation of estrone from blood¹² and it seemed possible to devise a similar method for the determination of both free and ester cholesterol. This paper describes such a method based upon adsorption on aluminum oxide and upon selective elution followed by estimation by the Liebermann-Burchard method.

METHOD

Principle of the Method.—Either plasma or serum is treated with a 1:1 acetone-ethyl alcohol solution and filtered. An aliquot of the filtrate is evaporated to dryness dissolved in petroleum ether, and placed upon an aluminum oxide column. The ester fraction is eluted with a 10 per cent solution of ethyl ether in petroleum ether, and the free cholesterol is then eluted with a 10 per cent solution of ethyl alcohol in petroleum ether. The cholesterol esters are then saponified and the free cholesterol in both fractions is determined colorimetrically, using cholesterol as the standard.

From the Department of Physiological Chemistry, Georgetown Medical School.
Received for publication, June 5, 1947.

Procedure.—To approximately 20 ml. of a 1:1 acetone-ethyl alcohol solution in a 25 ml. volumetric flask add 1.0 ml. of plasma or serum. The suspension is brought to boiling on the water bath, cooled, and made to volume with the acetone-alcohol solution and filtered.⁸ A 10 ml. aliquot of the filtrate is evaporated to dryness on the water bath and dissolved in 5.0 ml. of petroleum ether. The solution is placed upon the chromatographic column, containing 2.5 Gm. of aluminum oxide according to Brockman (Merck), and washed with 5.0 ml. of petroleum ether.¹² The ester fraction is eluted by the addition of 50 ml. of 10 per cent ethyl ether in petroleum ether. The eluate is collected and evaporated to dryness on a water bath. The free cholesterol is eluted with 25 ml. of 10 per cent ethyl alcohol in petroleum ether. This eluate is likewise evaporated to dryness.

The cholesterol ester fraction is dissolved in 10 ml. of 95 per cent ethyl alcohol and saponified by heating in an oven at 80 to 90° C. for ten minutes with 0.10 ml. of a potassium hydroxide solution (10 Gm. potassium hydroxide in 20 ml. water). This solution is neutralized with 10 per cent acetic acid in ethyl alcohol, using phenolphthalein as the indicator, one drop more than the required amount of acid is added. The solution is then evaporated to dryness on the water bath.

Both the free cholesterol and the saponified fraction are extracted with anhydrous chloroform and filtered into 10 ml. volumetric flasks. The filtrates are made to volume with chloroform. The reagent for color development is prepared by adding 1.0 ml. of concentrated sulfuric acid to 10 ml. of acetic anhydride. The acetic anhydride is chilled in an ice bath during the addition of the sulfuric acid and is kept there until used. The reagent is prepared fresh for each determination. To 5.0 ml. aliquots of the chloroform solutions is added 1.0 ml. of the reagent, and the color developed is read after standing for ten minutes. A Klett-Summerson colorimeter was used with either filter 54 or 42; the latter was found to be more sensitive.^{14, 15} The color is stable for at least ten minutes.

RESULTS

A standard solution containing 1.0 mg. of cholesterol in 5.0 ml. of petroleum ether was used to obtain a calibration curve. Aliquots of the standard solution were pipetted into colorimeter tubes, evaporated to dryness, and 5.0 ml. of chloroform added to each tube. Color development was carried out as described. The color obtained obeyed Beer's law in the concentration range of 0.02 to 0.50 mg. of cholesterol; above this concentration the color was too dense for accurate reading.

At the same time that the chromatographic separation was performed, another 10 ml. aliquot of the original plasma or serum filtrate was saponified and the total cholesterol determined by the method of Sperry and Brand.⁸

Accuracy of Separation of Cholesterol From Its Ester.—Cholesterol stearate was prepared by the method of Page and Rudy.¹⁶ A petroleum ether solution of the ester and cholesterol was prepared containing 1.0 mg. of cholesterol stearate (equivalent to 0.60 mg. cholesterol) and 0.2 mg. of cholesterol in 5.0 milliliters. This ratio represents approximately that found in normal human serum. Twelve separate determinations were made upon aliquots of the solution using the procedure described. The recovery of free cholesterol was 0.21 ± 0.01 mg., and of ester cholesterol, 0.57 ± 0.025 milligram. This represents an accuracy of approximately 5 per cent. It might be noted, however, that the ester recovery generally tended to be about 5 per cent low and the free cholesterol recovery was high by about the same amount. In a series of experiments with free cholesterol alone, a similar plus or minus variation was observed whether

the cholesterol was chromatographed or run directly. This error is probably inherent in the colorimetric method.

Recovery of Cholesterol Added to Blood Serum.—Since it was possible to separate cholesterol from cholesterol stearate in pure solution, the separation was next attempted in blood serum. The same serum was analyzed before and after the addition of the ester and cholesterol to the alcohol-acetone solution of the serum extract before filtering. In a 25 ml. flask were placed 15 ml. of the acetone-alcohol solution and 1.0 ml. of petroleum ether containing 0.4 mg. of cholesterol and 1.7 mg. of cholesterol stearate (equivalent to 1.0 mg. of cholesterol), and then 1.0 ml. of serum was added. The procedure as detailed previously was employed. The results of these experiments are given in Table I. Cholesterol can be separated from cholesterol ester in blood serum with the same degree of precision as in pure solution.

TABLE I. RECOVERY OF CHOLESTEROL AND CHOLESTEROL STEARATE ADDED TO BLOOD SERUM

SAMPLE	SERUM				RECOVERY	
	FOUND		FOUND AFTER ADDITION OF 0.40 MG. CHOLESTEROL AND 1.00 MG. CHOLESTEROL AS STEARATE		CHOL. (MG.)	ESTER (MG.)
			CHOL. (MG.)	ESTER (MG.)		
1	0.87	1.05	1.30	2.07	0.43	1.02
2	0.87	1.05	1.25	2.10	0.38	1.05
3	0.85	1.00	1.25	2.06	0.40	1.06
4	0.85	1.00	1.28	1.91	0.43	0.91
Average					0.41	1.01

In order to determine the reproducibility of the results, six separate determinations were made upon the same sample of blood serum. These results are given in Table II. The per cent of free cholesterol found varied from 33.3 to 36.6, with a standard deviation of 0.13 from the mean of 35.1 per cent. There is a deviation of 5 per cent from the mean for the highest and lowest values. The first column gives the data obtained upon the aliquot not chromatographed but analyzed after saponification by the method of Sperry and Brand.⁸ In general the agreement between this method and the chromatographic method is good.

Estimation of Cholesterol and Cholesterol Esters in Blood Serum and Plasma.—In Table III are presented the data obtained upon ten samples of normal serum, and in Table IV, upon twenty-five samples of blood plasma. The average total amount of cholesterol present as determined by the Sperry-Brand⁸ procedure is practically identical with the average total amount obtained by the chromatographic procedure, showing, at least, that there is no loss in the method. There is no significant difference in the ratio of free cholesterol to total cholesterol obtained in the plasma from that in the serum. The ratio is rather constant and is independent of the total amount of cholesterol present. As found by Schoenheimer and Sperry,³ using digitonin as the precipitant, it is 31.3 expressed as per cent, based upon the data from seventeen subjects. In a subsequent paper Sperry¹⁷ reported a value of 26.9 ± 1.4 per cent based upon data

*Method of Sperry and Brand.⁴

from sixty-two subjects, and he stated that with few exceptions values over 31 per cent were found only in the presence of infection or liver disease.

Using substantially the same method, Sobel and Mayer¹⁸ found the percentage of free cholesterol to total cholesterol to vary from 22.6 to 29.2. On the other hand, Page and co-workers¹⁹ found no such constancy of ratio, but their average value, based on data from sixty-six subjects, was 34.9 per cent free. Other workers²⁰ used digitonin to precipitate the free cholesterol, and the digitonide was estimated gasometrically. Folch and co-workers²¹ have stated that the gasometric values for free cholesterol are 20 per cent too high. Gardner and Gainsborough²² likewise used digitonin to precipitate free cholesterol which was then estimated colorimetrically and reported 35.3 per cent free cholesterol in twenty-one women and 33.8 per cent in twenty-two men. Recently Foldes and Murphy,²³ using digitonin precipitation, found an average of 33 per cent free cholesterol in the blood plasma of forty normal subjects. Although there appears to be some difference in the percentage of free cholesterol obtained by different laboratories using various methods, it is apparent that there is little disagreement over the fact that the percentage of free cholesterol is quite constant. The chromatographic method gives values for the percentage of free cholesterol within the range of those reported by others.

SUMMARY

Cholesterol and cholesterol esters adsorbed upon aluminum oxide from petroleum ether solution can be separated by selective elution. The ester fraction is eluted with 10 per cent ethyl ether dissolved in petroleum ether, and the free cholesterol with a 10 per cent solution of ethyl alcohol in petroleum ether.

The ester fraction is saponified and the free cholesterol in both fractions is determined by the Liebermann-Burchard colorimetric method. The method is rapid, approximately three hours are required for a complete determination, and the results are reproducible with an accuracy within 5 per cent.

The procedure has been applied to normal blood serum and plasma. The per cent of free cholesterol found in ten normal sera averaged 34.1 ± 4.9 per cent, and in twenty-five normal plasmas it averaged 35.8 ± 4.7 per cent of the total cholesterol.

RATES OF SODIUM TURNOVER IN NORMAL SUBJECTS AND IN PATIENTS WITH CONGESTIVE HEART FAILURE

GEORGE BURCH, M.D.,* PAUL REASER, M.D.,* AND
JAMES CRONVICH, B.E., M.S., S.M.†
NEW ORLEANS, LA.

THERE is a need for a study of the rate with which sodium escapes from the blood into the tissue spaces and urine of man, especially because of the present interest in the role of sodium in congestive heart failure and other types of edema. Although studies of sodium metabolism have been conducted in man by means of radiosodium,¹⁻⁴ these have not included a detailed tracing of the variations in sodium concentration in the blood, urine, and sweat. The rates of diffusion of sodium through the vascular wall have been determined for other animals^{5, 6} but not for man. Furthermore, tracer studies in congestive heart failure with the use of radiosodium have not been conducted previously. These studies are concerned with such problems.

METHODS

The subjects were all patients at the Charity Hospital. For purposes of discussion, the subjects were divided into three groups: normal subjects, those with congestive heart failure, and miscellaneous subjects. Certain detailed information concerning them is given in Table I. The ten normal subjects were patients who had entered the hospital for observation but were clinically well when studied. The patients with congestive heart failure suffered with chronic congestive heart failure of Functional Class IV and were bedridden. All were under treatment and were improving.

Because of the 14.8-hour half life of the radioactive tracer, Na^{24} , and the uncertainty of delivery from the cyclotron laboratories it was not possible to keep patients without treatment in preparation for the experiments. The influence of various therapeutic measures and other details concerning congestive heart failure were evaluated in studies conducted with the use of the long-life sodium, Na^{22} .^{7, 8} The results of those studies will appear from time to time elsewhere in a series of papers, one report⁷ having been published.

All subjects were at least three hours postprandial. They were taken to the laboratory where ureteral catheters were placed‡ into the pelves of each kidney of the normal subjects. The first subjects studied received no drugs in preparation for the cystoscopy while the later ones received morphine

Aided by a grant from the Life Insurance Medical Research Fund, Helis Institute for Medical Research, and the Mrs. E. J. Caire Fund for Research in Heart Disease.

Received for publication, July 25, 1947.

blood the t were those made at the time of admission to the Charity Hospital for study.

f the sodium (Na²³) in the urine was determined on the basis of a normal subjects were clinically well when studied; the diagnoses indicated

sulfate, 15 mg., and atropine sulfate, 0.3 mg. subcutaneously thirty minutes before the cystoscopy. The results showed evidence of influence by the drugs used in preparation of the subjects for cystoscopy. The patients with congestive heart failure and two normal subjects had a small catheter passed only into the bladder. The patients with congestive heart failure were too ill to permit a cystoscopy to place catheters into the renal pelvis. Bladder urine was about as informative as the pelvic urine.

After catheterization, a sample of urine was collected from each catheter and a sample of blood was collected simultaneously from the antecubital vein of one arm through a heparinized needle. The radioactive tracer, Na²⁴ (0.5 to 2 c.c. of a neutral and hypotonic aqueous solution of NaCl), with an activity

of 20,000,000 counts per minute (approximately 0.1 mc. or 0.04 r) was injected quickly into the antecubital vein of the opposite arm. Two cubic centimeter samples of blood were collected for serum studies as rapidly as possible, every five to ten seconds unless the needle became obstructed and necessitated a greater interval between collections. This rate of collection was followed for the first three minutes after the injection of the Na^{24} . The interval between collections was increased to thirty seconds for the next five minutes, increased again to every sixty or 120 seconds for the next ten minutes, and finally, to every three, five, or ten minutes for the remainder of the study, which lasted from sixty to one hundred eighty minutes. The urine samples were collected from each catheter in separate vials. For the first three minutes the interval between collections of the urine samples varied with the rate of urine flow, that is, long enough for four drops of urine to be collected. This usually required five to fifteen seconds. For the next five minutes collections were made at thirty-second intervals, etc., as for the blood samples. Attempts were made to collect the blood and urine samples at the same time in order to permit satisfactory comparisons. The volume of the urine samples was measured to determine the sodium (Na^{24}) clearances from collection to collection. The urine samples collected from the pelvis of each kidney were studied separately.

In several experiments samples of edema fluid were collected simultaneously through a puncture wound made through the skin near the ankle with an 18-gauge needle. The rates of collection approximated those for the blood and urine. Simultaneous collections of successive samples of ascitic and pleural fluid in subjects with congestive heart failure were made to study the change in concentration of Na^{24} .

One normal subject was placed in a hot and humid room (temperature, 48°C .; relative humidity, 45 per cent) free from drafts. After sweating had become profuse the procedure described above was followed except that the urine was collected at less frequent intervals while the blood and sweat samples were collected at the rapid rates stated previously. The sweat was collected by allowing the beads of sweat to roll into the opening of a tall narrow-mouthed vial which was promptly closed with a bakelite screw cap. Each sample of sweat consisted of about 0.1 cubic centimeter. These collections were continued for about thirty minutes, that is, until the subject and observers began to experience marked discomfort from the hot and humid environment.

The concentration of Na^{24} in all samples was expressed as counts per cubic centimeter per minute. Geiger-Muller counters* were used to determine radioactivities of the injections and the samples. Corrections were made for background counts and decay. The entire counting method had an over-all error of less than 3 per cent. All dosages of Na^{24} were reduced to the common value of 20,000,000 counts per minute per 100 pounds of weight.

RESULTS

Normal Subjects.—The results for the normal subjects are summarized in Figs. 1 to 6.

*Technical Associates, Glendale, Calif.

Blood: It can be seen from Fig. 1 that the concentration of the Na^{24} rose rapidly in the blood serum, fluctuating in concentration for the first five to fifteen minutes and then becoming relatively constant for the remainder of the period of observation. The concentration of Na^{24} did not rise to levels as high as would be expected if all the Na^{24} remained in the blood stream. There was a tendency for the concentration of Na^{24} in the serum of most of the subjects to rise for the first ten to twenty minutes to levels higher than those reached during the final periods of the study and to show marked variations from subject to subject. There was a gradual decline in the serum concentration of Na^{24} in all subjects throughout the entire period of study even after a fairly stable state had been reached. The Na^{24} did not appear in the antecubital vein of the sampling arm until nineteen to twenty-three seconds after the radiosodium had been injected into the antecubital vein of the other arm, that is, by a time equal to the circulation time.

Fig. 1.—Variations in serum concentration of Na^{24} in ten normal subjects. There are considerable individual variations, especially during the first two to three minutes when the mixing of the injected radiosodium is occurring.

Because of the marked variations in concentration of Na^{24} in the serum of the subjects and because of the small number of subjects studied, it was impossible to obtain a composite tracing which properly depicted the rate of diffusion of sodium from the vascular bed (Fig. 1). Therefore, the data on a subject (Subject 6) were selected for analysis in the manner described by Gellhorn and co-workers;⁵ all diffusion curves were drawn by inspection. These authors showed that the vascular bed of dogs could be considered to be composed of two separate areas through which the sodium ion diffuses at different rates. Area A_1 consists of an area through which the sodium diffuses at a very rapid rate, while A_2 represents another area through which the rate of diffusion is relatively slow. The same types of areas were observed in these studies in the normal and diseased man. Fig. 2 can be seen to represent a typical double exponential curve for the blood concentration. There was a rapid rate of escape of Na^{24} from the vascular bed and a slow one. The general expression obtained by Gellhorn and co-workers⁵ for dogs, and found to apply to man in many of the subjects of this study, is

$$c_p - c_{eq} = a_1 e^{-b_1 t} + a_2 e^{-b_2 t} \quad (1)$$

where c_p is plasma concentration of Na^{24} at time, t , c_{eq} is plasma concentra-

tion at equilibrium, b_1 and b_2 are rates of diffusion from the vascular bed, and a_1 and a_2 are coefficients which depend upon the rates of movement and distribution of Na^{23} through areas A_1 and A_2 in the vascular bed. Since the diffusion of Na^{24} is determined by the diffusion of Na^{23} , the exponents b_1 and b_2 are expressions of the rates of diffusion of the total plasma sodium (Na^{23}) out of the vascular bed. Therefore, it is possible to consider the sodium of the plasma as being divided into three parts: one represented by a_1 , which diffuses outward rapidly through area A_1 ; a second represented by a_2 , which diffuses outward at a relatively slow rate through area A_2 ; and a third represented by c_{eq} , which remains in the plasma.

Fig. 2.—Variations in serum, urine, and sweat concentrations of Na^{24} and the Na^{24} clearance in normal Subject 6. The curve of blood concentration is a double exponential curve representing sodium diffusion, the equation of which is shown, *L.K.*, Left kidney.

To determine the rate of loss by diffusion of the total plasma sodium, the equation

$$\frac{-a_1b_1 - a_2b_2}{c_0} = R_p$$

is employed, where c_0 is the extrapolated initial count per minute per cubic centimeter of the plasma.

The expression for radioactive sodium concentration in the plasma for Subject 6 (normal) was

$$c_p - 1600 = 2873e^{-0.582t} + 966e^{-0.0641t}. \quad (2)$$

Thus 58 per cent of the rapidly diffusing sodium left the plasma per minute, and 6.4 per cent of the slowly diffusing sodium left the plasma per minute. Considering the sizes of these sodium compartments in the plasma, an average of 32 per cent of the total sodium in the plasma diffused out of the vascular bed per minute.

Furthermore, Merrell and associates⁶ have shown that from the same data the rate of diffusion of sodium from the extravascular fluid* back into the plasma at equilibrium could be determined by the equation

$$R_0 = R_p \frac{(1-q)}{q}$$

*The term extravascular sodium employed here probably is concerned predominantly with interstitial fluid sodium because of the relatively short duration of the studies. For that reason interstitial and extravascular sodium is considered essentially synonymous in these studies.

where R_e = rate at which the extravascular sodium returns by diffusion into the plasma, R_p = rate of loss by diffusion of the total plasma sodium in the vascular bed, and q = total extravascular sodium. The values obtained for Subject 6 are shown in Table II. It is noted that about 32 per cent of the total sodium in the plasma diffused into the interstitial fluid per minute and that 13 per cent of the total sodium in the interstitial fluid returned by diffusion to the plasma per minute.

TABLE II. PROPORTION OF SODIUM DIFFUSION IN FOUR HUMAN SUBJECTS

	NORMAL SUBJECT 6	CONGESTIVE HEART FAILURE SUBJECT 3	1	MISCELLANEOUS SUBJECT 5
Proportion of total sodium in interstitial fluid	0.70	0.89	0.90	0.65
Proportion of total plasma sodium diffusing out of vascular bed per minute	0.32	0.63	0.54	0.35
Proportion of total interstitial fluid sodium diffusing into the vascular bed per minute	0.13	0.08	0.06	0.18

 Fig. 3.—Variations in urine concentrations of Na^{24} in ten normal subjects.

Urine: The concentration of radioactive sodium in the urine exceeded that in the blood serum in three subjects (Fig. 3). In most cases the blood and urine concentrations were essentially equal, although the urine concentration was definitely lower in Subject 6. The urine concentration varied much more than did the blood concentration after the initial few minutes following the injection.

Sodium Clearance: The sodium clearances for five normal subjects are shown in Figs. 4, 5, and 6. Na^{24} clearances were employed in these analyses since they integrated volume of urine flow and blood and urine concentrations. The exact significance of these values for a substance like sodium is not known. They do make certain comparisons feasible. These values were calculated in a manner similar to that used for the urea clearance.

The equation for the calculation is

$$\text{Na}^{24} \text{ clearance} = \frac{\text{Na}^{24} U_r}{\text{Na}_{b,24}} \quad (3)$$

Fig. 4.—Variations in Na^{24} clearance in five normal subjects. Since the movement of Na^{24} around the body is determined by the movement of Na^+ , these curves represent rates of Na^{24} clearance once equilibrium has been reached.

Fig. 5.—Variations in serum and urine concentration (left kidney) of Na^{24} , and Na^+ clearance for both kidneys separately in one subject. Note the marked variations in serum concentration during the first three minutes. The serum concentration then settled down to a diffusion type of curve as shown for normal Subject 6 (Fig. 3). The mixing phenomenon was relatively poor for the first three minutes in Subject 7, but early and adequate for Subject 6. Such chance variations are to be expected. Note the concordant and only occasional discordant relationship of the Na^{24} clearances in the urines of the right and left kidneys.

Fig. 6.—The average and extreme (within parentheses) values for Na^{24} clearance in the three groups of subjects. It is necessary to remember that the patients with congestive heart failure were on a slow sodium diet.

where Na_u^{24} = counts per cubic centimeter of urine, Na_b^{24} = counts per cubic centimeter of blood, and U_v = volume of urine flow per minute.

Except for Subject 7 the rates of Na^{24} clearance were fairly constant and of essentially the same magnitude. They tended to average 0.22 c.e. of blood cleared per minute per kidney but were high for Subject 7, reaching a level of about 2.4 c.e. of blood cleared of Na^{24} per minute for both kidneys. Figs. 4, 5, and 6 show the quantitative and qualitative variations in the clearances for both kidneys observed separately and simultaneously.

Comment: The levels of Na^{24} concentration in the blood serum should have reached values of about 10,000 counts per minute per cubic centimeter if all of the injected materials had remained in the blood. Instead, the concentrations actually reached averaged about 2,500 counts per minute per cubic centimeter, with the maximum being 4,600. The average curve for the normal subject shows a tendency for the concentration of Na^{24} in the blood to reach the final concentration level rapidly and not to exceed it appreciably. This indicates the very rapid rate of diffusion of sodium from the blood. In fact, the diffusion is so rapid that the circulation of the blood is too slow to permit adequate mixing before a considerable amount of diffusion occurs. The relatively marked variations in Na^{24} concentration in the blood observed during the first few minutes of the study are due in a large part to inadequate mixing. Adequate mixing does not appear to be completed in some subjects before ten minutes have elapsed (Fig. 1). As stated previously, the marked variations in the rates of mixing of the blood made it impossible to determine the average diffusion rates for the normal subjects as a group. From the analysis of the data of Subject 6 it was found that sodium diffused across the vascular bed at two separate rates. This diffusion outward resulted in a loss per minute of about 0.6 of the rapidly diffusing and of about 0.06 of the slowly diffusing plasma sodium. The average rate of diffusion of sodium from the vascular bed was 32 per cent of the total plasma sodium per minute. This is equal to about 4,000 Gm. of sodium per day for a man weighing 70 kilograms. These results are remarkably similar to those observed in dogs by Gellhorn and associates.⁵ It is interesting to note that if the Cl ion tends to follow the Na ion during its diffusion, this would entail a diffusion of about 10,000 Gm. of NaCl out of the vascular bed of the average man per day. The amount of sodium returning is, of course, the same. Thus there is a diffusion of about fifty pounds of NaCl back and forth through the capillary wall per day in a man weighing 70 kilograms.

It is generally agreed that the rapid diffusion of sodium is into the interstitial fluid.⁵ The slower diffusion must take place into bone,^{2,9} cerebrospinal fluid,¹⁰ chambers of the eye,¹⁰ and other structures of the body which allow relatively slow rates of sodium exchange. It is also important to know the rate of diffusion of water across the vascular bed. Merrell and co-workers⁶ observed that 1.46 of the plasma water diffused out into the tissues of the guinea pig per minute. Since comparable values were obtained for the rates of diffusion of sodium in guinea pigs, dogs, and man, it is likely that the rates of diffusion of water should be similar. If the same rates are applied for man as were

found in the guinea pig, then about 6,300 liters of water per day diffuses out of the vascular bed of a man weighing 70 kilograms. It is obvious from the diffusion rates for sodium and water that water diffuses more rapidly. Not only has this been observed for the body as a whole, but for isolated tissues as well. Kinsey and associates^{10, 11} found this to be true for the vitreous body and aqueous humor of the eye of the rabbit. It has also been noted for the cerebrospinal fluid.¹²

Although the Na^{24} concentration in the blood serum reached a level free from marked fluctuations within a few minutes, the concentrations progressively decreased and did not reach a state of equilibrium by the end of two hours, even though corrections were made for loss of Na^{24} in the urine. These findings, therefore, indicate that the Na^{24} rapidly reaches equilibrium with the interstitial fluid. This represents the greatest portion of the Na^{24} injected. Then for several hours there is a gradual passage of the Na^{24} into bone, spinal fluid, vitreous body, aqueous humor, and similar sodium compartments.⁹⁻¹¹ Therefore, studies which require a complete state of equilibrium with radio-sodium for all structures of the body must be conducted several hours after the injection of the tracer. The measurement of the sodium compartment of the body cannot be measured properly until the tracer has reached a state of equilibrium for all structures of the body. For that reason any estimate of the sodium compartment with the use of Na^{24} in the studies reported here is subject to error and therefore has limited significance.

The urine concentration of Na^{24} varied considerably from subject to subject. These differences must be related, in part, to the sodium intake preceding the experiments. The cause of the delay in the appearance of the Na^{24} in the urine is unknown. It must be due partly to the time required for the urine to flow from the glomerulus to the outlet of the catheter. However, this requires only about thirty seconds. The delay might be due in part to diffusion from the blood into Bowman's capsule, but the rapid appearance of Na^{24} in the sweat and the rapid diffusion into the interstitial fluid tends to eliminate such a delay as an important factor. The effect of pooling of urine in the pelves of the kidneys could not be evaluated.

Although the data are not shown for both kidneys separately, for all subjects the rates of excretion of Na^{24} were essentially the same for both kidneys. Although there were periods when the rates of excretion and Na^{24} concentration showed discordant relationships, the behavior was so similar as to make it unnecessary to report the data for both kidneys separately. Subject 7 (Fig. 5) exemplified the individual kidney relationships. Since the Na^{24} clearances are reported for only one kidney, the total clearances are essentially twice that shown for one kidney.

Although the concentration of Na^{24} in the urine varied quite markedly (Fig. 3), the rate of Na^{24} clearance was fairly constant. This indicates that when the volume of urine flow was great, the concentration of Na^{24} in the urine was proportionately low and vice versa.

Subjects With Congestive Heart Failure.—The results obtained in the subjects with congestive heart failure are summarized in Figs. 6 to 11.

Blood: There was a tendency for the concentration of Na^{24} in the blood serum to reach a higher level in the subjects with congestive heart failure than in the normal subjects (Fig. 7). Marked fluctuations were noted for the first ten to twenty minutes; then a stable level was reached. The injected Na^{24}

Fig. 7.—Variations in serum concentration of Na^{24} in eight patients with congestive heart failure. If the presence of a diffusion type of sodium curve indicates adequate and early mixing of the injected radiosodium, then mixing appears to have developed more quickly in these persons than in the normal ones.

Fig. 8.—Variations in serum, urine, and edema fluid concentration and Na^{24} clearance in Patient 3 with chronic congestive heart failure. The serum concentration curve is a typical double exponential diffusion curve, the equation of which is shown. Note the fairly rapid increase in concentration of Na^{24} in the edema fluid to a level equal to that in the serum.

appeared in the antecubital vein of the sampling arm a few seconds later than in the normal subjects. Like the normal subjects, the patients with congestive heart failure showed such wide variations in the serum concentrations of Na^{24} that it was impossible to calculate a satisfactory average diffusion pattern for the Na^{24} . Some individuals, however, presented typical diffusion curves with

Fig. 9—Variations in serum and urine concentration of Na^+ and Na^+ clearance in Subject 1 with congestive heart failure. The equation for the sodium diffusion curve is shown.

Fig. 10—Variations in urine concentration of Na^+ in eight patients with congestive heart failure and a low sodium diet. Compare these values with those for the normal (Fig. 3).

Fig. 11—Variations in Na^+ clearance in eight patients with congestive heart failure and a low sodium diet. Compare these values with those for the normal (Figs. 4 and 6).

both rapid and slow rates of diffusion of sodium from the blood plasma (Fig. 8). The equation for the diffusion curve of Fig. 8 was found to be:

$$c_p - 1000 = 6230e^{-0.915 t} + 2015e^{-0.094 t}. \quad (4)$$

This indicates that 0.915 of the plasma sodium which diffuses at the rapid rate escaped from the vascular bed into the interstitial spaces per minute, and 0.094 of the plasma sodium which diffuses at the slow rate escaped from the vascular bed per minute. Because of the rapid rate of diffusion in Subject 3, another patient (Subject 1) with congestive heart failure was similarly studied (Fig. 9). The curve for this patient had the following equation:

$$c_p - 1100 = 8450e^{-0.700 t} + 1510e^{-0.068 t}. \quad (5)$$

The diffusion rates in this subject were about the same as for the normal subject, although still more rapid.

From Table II it can be seen that 54 and 63 per cent of the total plasma sodium diffused out of the vascular bed per minute as average rates in Subjects 1 and 3, respectively. Simultaneously 6 and 8 per cent of the total interstitial fluid sodium diffused back into the plasma per minute in the respective patients.

Urine: The urine was collected from the bladder and not directly from the renal pelvis as in the normal subjects. The results are summarized by Figs. 8, 9, and 10. The Na^{24} did not appear in the urine until four to five minutes after injection except in one patient (Fig. 10). The concentration of Na^{24} rose more slowly and the concentration levels reached were much lower than in the normal subjects. Considerable fluctuations were observed during the initial twenty to thirty minutes of study, followed by a stable level with minor variations of essentially the same degree as those encountered in the normal subjects.

Sodium Clearance: The sodium clearances of the patients with congestive heart failure with therapy are summarized in Figs. 6, 8, 9, and 11. The rates by which the blood was cleared of sodium were considerably lower than those observed for the normal subjects. These clearance values for both kidneys were about 0.03 c.e. per minute, the quantitative and qualitative variations being shown in Fig. 11. The clearance values approached zero in some subjects (Subjects 1, 2, and 3).

Edema Fluid: It was possible to follow the appearance of Na^{24} in the edema fluid of most of the patients with congestive heart failure. The results of the study of the edema fluid of Subject 3 are shown in Fig. 8.

Comment: The rapid and slow rates of diffusion of sodium from the vascular bed of the patients with congestive heart failure were higher than those observed in the normal subject. Obviously, it is not possible to conclude that such a difference is characteristic of congestive heart failure. Too few subjects were studied and too many factors are concerned with the escape of the sodium ion into the tissues for one to conclude that a greater rate of transcapillary diffusion is at work in all patients with congestive heart failure. The problem of mixing of the blood and the general inefficiency of the circula-

tion are important in congestive heart failure. Furthermore, it is necessary to bear in mind that all of the patients with congestive heart failure were receiving therapy. One aspect of the therapy (ammonium chloride and mercurial diuretics) was intended to make the kidneys excrete more sodium, while another phase of the therapy (dietary restriction of sodium) resulted in a decreased rate of renal excretion of sodium. The influence of these factors on the data obtained is unknown, but they were most probably great enough to make it impossible to evaluate the role of uncomplicated congestive heart failure on transepillary diffusion of sodium. Gellhorn and associates⁵ found the rates of transepillary diffusion in dogs in shock, with and without treatment, were 50 per cent of those of normal dogs. Of course, the disturbances in hemodynamics are quite different in shock and in chronic congestive heart failure without shock.

Nevertheless, the more rapid rate of diffusion of sodium across the vascular wall in congestive heart failure than in the normal condition can be explained by the fact that there is a greater quantity of total amount of extracellular fluid and, therefore, of sodium in the edematous patients. Inspection of Table II shows that the part of the total extracellular fluid sodium of the patient with congestive failure diffusing back into the vascular bed per minute is about 50 per cent of that of the normal. The total quantity of sodium concerned, however, is greater than normal. Since the same quantity of sodium returns to the circulation as leaves it per unit time and since the increase in blood volume is not proportional to the increase in volume of the interstitial fluid, it is necessary that the plasma sodium diffuse more rapidly than in the normal subject in order to maintain a state of equilibrium. Thus the sodium of the interstitial fluid of the normal subject is turned over twice as rapidly as in the patients with congestive heart failure, whereas the sodium of the plasma of the latter patients is turned over twice as rapidly as that of the normal.

The rise in the concentration of Na^{24} in the edema fluid (Fig. 8) is an index of the rate of diffusion of normal sodium, Na^{23} , into edema fluid from the vascular bed. This rate is relatively high when the quantity of the edema fluid is considered. The concentration of the Na^{24} in the edema fluid reached that in the plasma, remaining near the plasma level thereafter. The duration of the rising periods of the Na^{24} concentration in the edema fluid is further support of the relatively long period of time required for a state of sodium equilibrium to be reached when tracer studies are done. This is particularly true when certain abnormal states are under observation.

Miscellaneous Subjects.—

Blood and Urine Concentrations and Sodium Clearance: The results are summarized in Figs. 12 to 15. The nature of the variations in Na^{24} concentration in the blood and urine and Na^{24} clearances was essentially the same as for the normal subjects and those with congestive heart failure, differences being determined by the underlying disease state. For example, Subject 1 suffered with congestive failure due to essential hypertension and was under treatment

Fig. 12.—Variations in serum concentration in five patients with miscellaneous disease states (Table I).

Fig. 13.—Variations in serum concentration, urine concentration, and Na^{24} clearance in a patient with chronic phlebothrombosis of both legs and moderate chronic edema. The diffusion curve for sodium and its equation are shown.

for the heart failure. She also had a fairly extensive ovarian malignancy. The variations in Na^{24} concentration in the blood and urine and in the sodium clearances were similar to those described for the group of patients with uncomplicated congestive heart failure under treatment. The patients with phlebothrombosis and sarcoidosis were not found to show any special characteristic behavior.

Subject 5 with phlebothrombosis was selected for analysis of the diffusion rates of sodium because the edema was limited to the two lower extremities and because the data were suitable for such an analysis. The curve (Fig. 13) representing variations in the serum concentration of Na^{24} is similar to that

of the normal subject and the subjects with congestive heart failure. The curve of the serum concentration may be expressed as

$$c_p - 1700 = 1915e^{-0.875 t} + 1290e^{-0.051 t}, \quad (6)$$

that is, 0.875 of the plasma sodium which diffuses through area A_1 left the blood per minute, while 0.051 of the plasma sodium which diffuses through A_2 left the blood per minute.

Fig. 11.—Variations in urine concentration of Na^{24} in four patients with miscellaneous disease states.

Fig. 15.—Variations in Na^{24} clearance in four patients with miscellaneous disease states. * Compare these values with those of the other two groups of subjects (Figs. 4, 6, and 11).

Comment: Fever and other systemic influences from infection, malignancy, or sarcoidosis did not present any detectable influences on the diffusion of sodium through the vascular bed. The rate of excretion through the kidneys, however, might conceivably be influenced by renal damage as well as by therapy. The rates of sodium diffusion were too high to permit minor variations to manifest themselves sufficiently for detection.

The transepillary diffusion of sodium in these subjects indicated at least two rates, a rapid and a slow one. In the subject with phlebothrombosis the rates of diffusion through areas A_1 and A_2 were of the order encountered in the two patients with congestive heart failure. The patient with phlebothrombosis

was receiving only bed rest; no therapy was directed at the edema specifically. Table II indicates the proportion of plasma and interstitial sodium diffusing through the vascular bed per minute.

Concretio Cordis and Marked Ascites: Miscellaneous Subject 7 had marked chronic cardiac tamponade with marked ascites and was receiving therapy for congestive heart failure. The therapy included the use of digitalis, mercurial diuretics, and a low sodium diet. He died at operation several days after this study and a thick fibrous sheet, which interfered markedly with diastolic filling of the heart, was found to encase the heart. He was studied in the manner previously described except that an 18-gauge needle was placed into the peritoneum so that samples of ascitic fluid could be collected at frequent intervals for study. The relative concentrations of Na^{24} in the blood and ascitic fluid are shown in Fig. 16. There was a very slow but definite rise in the Na^{24} concentration in the ascitic fluid. This rise was much slower than that observed in the urine or edema fluid of the other patients. The blood serum concentration of Na^{24} showed the usual variations.

Fig. 16.—Variations in serum and ascitic fluid concentrations of Na^{24} in a patient with concretio cordis and marked ascites. Note the relatively slow increase in the Na^{24} concentration in the ascitic fluid as compared with that of the edema fluid of Subject 3 with congestive heart failure.

Comment: The relatively slow diffusion of Na^{24} into the ascitic fluid of this patient is probably due to the great mass of fluid through which the Na^{24} must diffuse, as well as a less rapid diffusion of sodium through the peritoneal membrane. The importance of the former factor is supported by the slow diffusion into the edema fluid. The tissues are richly supplied with capillaries which permit a larger area of contact with the interstitial fluid; that is, the ratio of area of capillary wall in contact with each unit volume of fluid is high. The capillary area of contact per unit volume of edema fluid is less and, therefore, a longer time is required for equilibrium to be established. In the case of the ascitic fluid the ratio of capillary wall per unit volume of fluid into which diffusion occurs is considerably less and, therefore, the slower diffusion and even longer time required for equilibrium to be established becomes evident. There is no doubt that the stirring of the edema fluid that occurs with breathing and movement of the body aids in increasing the rate with which the state of equilibrium is reached. These observations further support the evidence that several hours are required to reach equilibrium, especially in edema states, after radiosodium tracer studies are conducted.

Excretion of Na^{24} by the Sweat Glands: A normal subject (a 45-year-old white man) rested in a hot and humid air-conditioned room (temperature, 48°C .; relative humidity, 45 per cent). After the bladder was emptied he was studied in the same manner as described for the other subjects.

Results: The results are summarized in Fig. 17. The Na^{24} appeared in the sweat in seventy-five seconds after the intravenous injection. The concentration of Na^{24} was greatest in the blood and least in the urine. The concentration in the sweat tended to follow that in the blood very closely. Unfortunately the subject could not remain very long in the hot and humid atmosphere; therefore, the experiment was stopped after only thirty minutes of observation. Another sample of urine and of blood, collected about forty minutes after the subject was removed from the hot room, showed no special change in Na^{24} concentration. Concentrations of Na^{24} in the urine, blood, and sweat of normal Subject 6 are shown in Fig. 2. Six samples of sweat were measured during the period of study.

Fig. 17.—Variations in serum, sweat, and urine concentrations of Na^{24} in a normal subject who was in the process of profuse thermal sweating when the Na^{24} was injected intravenously.

Comment: These data show the rapid rate with which sodium reaches the sweat. When a correction is made for circulation time, sodium is found to diffuse from the plasma into the interstitial spaces, enter the cells of glomerulus of the sweat glands, be made into sweat, and delivered to the surface of the body in less than sixty seconds. Fig. 17 suggests many interesting concepts of integrations of urinary, sweat, and plasma sodium concentrations. Any

comments based on one experiment would have little significance. More extensive studies will be described at a later date.

GENERAL DISCUSSION

The diffusion of sodium through the vascular bed in man behaves in a manner similar to that described by Gellhorn and associates for guinea pigs and dogs.⁴⁻⁶ For comparison the vascular bed can be divided into at least two areas, A_1 and A_2 , through which diffusion occurs at two very different rates. The more rapid rate of sodium exchange, through A_1 , takes place between the plasma and the intercellular fluid. The slower rate of exchange, through A_2 , occurs between the plasma and such fluids as that of the vitreous body, aqueous humor, cerebrospinal fluid, and probably the intracellular fluid. Inspection of the regression curves shown indicates a third main, and even slower, rate of diffusion which may occur between plasma and bone, dentin, and enamel.⁹ This area of the vascular bed through which this occurs might be referred to as A_3 . There is no doubt that there are *many* other differences in rates of diffusion of sodium between the plasma and other structures of the body, the number being limited by the sensitivity of the method of analysis. Under different states of salt intake, nutrition, glandular secretion, vasomotor function, and disease these rates are altered. For example, there is a different rate of diffusion into edema fluid (Fig. 8) from that into ascitic fluid (Fig. 16). A generalized edema state results, therefore, in two areas in the vascular bed with different rates of diffusion. At the present time it is much better to consider the vascular bed as having two main areas with diffusion at a rapid rate and at a slow rate, these being summations of many different rates of diffusion. It is necessary to remember that this may be an oversimplification of the problem and that with further study other rates will be defined.

The rate of the circulation in man is relatively slow when compared with that which would be desirable to insure adequate mixing for proper study of a substance which diffuses as rapidly as sodium. The mixing time in the average person is so long and the diffusion of sodium out of the blood vessels so rapid that in most cases data were obtained which did not lend themselves to detailed mathematical analysis. In some experiments, however, the mixing was rapid and adequate so that a mathematical analysis was possible. Several of these were selected for such a study. The period during the first minute after the injection was not suitable for proper study of diffusion because slow mixing and rapid diffusion complicated the diffusion pattern. The dashed lines in Figs. 2, 8, 9, and 13 show the rapid increase in the concentration of Na^{24} in the blood within the first minute or two after the injection of the radiosodium, during which time the regression curves are modified to an unknown extent. The remaining portion of the curves is a more accurate representation of the facts. There is no doubt that if there are any errors, such as those due to slow mixing, they are concerned with factors which tend to make the observed b_1 , the rapid rate of diffusion of sodium, smaller than it actually is. The values for b_2 , the slow rates of diffusion, are most probably near the

true rate since mixing interferes little with the latter portions of the regression curves. Furthermore, since a state of equilibrium had not been fully reached by the end of ninety minutes, the equilibrium values, c_{eq} of equations (2) and (5), are not the true equilibrium values. Studies⁴ with the long-life sodium, Na^{22} , in other subjects have shown the true c_{eq} , the equilibrium constant, to be near those employed in the regression curve formulas, however.

The coefficients, a_1 and a_2 , of the various regression curves are dependent upon such factors as rates of diffusion, size of the areas A_1 and A_2 , and the distribution of the sodium. Therefore, a_1 and a_2 can represent only roughly the degree of distribution of Na^{21} in the two compartments of the body, that is, the one which is concerned with a rapid rate of diffusion of sodium and the other with a slower rate. An index of the volume of the blood plasma should be c_0 , the value of c_p at $t = 0$, but because of the difficulties introduced by slow mixing it is difficult to interpret.

The rates of diffusion appear to be quite variable among the individuals of all groups studied (Figs. 1 and 7). The rates of diffusion through areas A_1 and A_2 were definitely greater in the patients with congestive heart failure than in the normal subjects. Because of the marked variations and the relatively small number of subjects studied, it is not possible to be certain of the significance of these differences. However, as indicated previously, this is expected because of the greater absolute quantities of interstitial fluid and, therefore, of sodium in the patients with congestive heart failure. The turnover of the interstitial sodium in the patients with congestive heart failure is essentially half as rapid as in normal subjects, while the plasma sodium turnover is twice as rapid in the patients with congestive heart failure as that in the normal subjects.

The patients with congestive heart failure were too ill to permit the insertion of ureteral catheters into the pelves of the kidneys. A small urethral catheter was placed in the bladder instead. This resulted in a satisfactory study of Na^{24} excretion in the urine but did not present the advantage of studying each kidney separately. All sodium clearances for the patients with congestive heart failure represented total clearance, while those in the normal subjects represent unilateral clearance, or essentially one-half of the total clearance (Fig. 6). This should be remembered when examining the illustrations and when comparing the rates of clearance in the normal and abnormal subjects.

The radiosodium was excreted in essentially the same concentration and at the same rate by both kidneys. There was a tendency at times, however, for one kidney to excrete more rapidly than another, but this was varied throughout the period of study. Although the concentration of Na^{24} and the rate of sodium clearance tended to vary concordantly, there were sufficient variations to indicate differences in function between two contralateral normal kidneys. Although both are under the same general hormonal or chemical and nervous influences there were individual differences. Most of these differences must result from differences in intrinsic renal function. In some isolated instances these differences were considerable, although the excretion of Na^{24} usually differed very little in the two kidneys.

The rate of sodium clearance was much slower in the patients with congestive heart failure than in the normal subjects. This is particularly significant when the rapid transepillary diffusion rates are considered. It was impossible to evaluate the differences between the two groups of subjects because the patients with congestive heart failure were receiving treatment for the failure. This treatment included dietary restriction of sodium, a procedure normally associated with a decrease in renal excretion of sodium. Nevertheless, these differences are largely due to the congestive heart failure, as evidenced by previous studies⁷ with Na^{22} and to the fact that three of the patients with a low sodium clearance had not been on sodium restriction for more than twenty-four hours before the study was begun. The long life of Na^{22} made it possible to control sodium intake, therapy, diet, and other factors in order to evaluate better the disturbances in sodium excretion in congestive heart failure. Unfortunately, this was not possible in these studies with Na^{24} .

Table I shows estimations of sodium space. A sodium space calculated within one or two hours after injection cannot be accurate. This is obvious from the preceding discussion of the rapid rate of diffusion of sodium and the relatively long time required for a state of equilibrium or "complete mixing" of the Na^{24} with all of the Na^{23} distributed through the body to occur. The inaccuracy of such a calculation is further indicated by Table I. The sodium space calculated from data at the sixtieth minute after injection of the Na^{24} was lower than that calculated at the ninetieth minute. Furthermore, radio-sodium cannot be employed to measure extracellular water volume with any degree of accuracy because a fairly large portion of the body sodium is not in the extracellular water. The method becomes even more inaccurate in disease states, especially in those associated with edema. The values of sodium space presented in Table I are intended only to illustrate the possible error of such a calculation and not to present absolute values of sodium space. The lower equilibrium level, c_{eq} , for the patients with congestive heart failure and the larger values obtained for the estimated sodium space in these patients are quantitative evidence of the large edema fluid volume accompanying congestive heart failure.

The rapid rate and high concentrations with which Na^{24} appeared in sweat is further evidence in support of the rapid rate of diffusion of sodium across the vascular wall. The relationships of sodium in the sweat, urine, blood, and edema fluid are under study. The single study presented is not sufficient to warrant any definite physiologic conclusions, although many ideas are suggested.

Finally, it is important to note that the rapid rates of sodium and water diffusion and the tremendous quantities concerned make the problem of the mechanism of edema assume a different pattern. Sufficient evidence has not been gathered yet to make possible a proper appreciation of the role of the rapid and large turnover of sodium and water in edema formation. It is obvious that slight disturbances in sodium diffusion or excretion might result in a rapid and marked accumulation of edema fluid. These factors are now under observation.

SUMMARY

Normal subjects, patients with congestive heart failure under treatment, and patients with other disease states were studied following a single intravenous injection of Na^{24} to learn the rate of diffusion of sodium through the vascular wall and its rate of excretion into the urine and sweat.

Sodium diffuses through the vascular wall with at least two rates, *rapid* and *slow*. These rates of diffusion of sodium in man are similar in quantity and quality to those described by Gellhorn and associates for guinea pigs and dogs. In a normal subject the average rate of diffusion indicated that about 32 per cent of the total plasma sodium diffused out of the blood every minute. This approaches a diffusion across the vascular wall equal to about 18 pounds of sodium or 50 pounds of sodium chloride per day.

The sodium that diffuses at a rapid rate is mainly concerned with an exchange between the plasma and interstitial fluid, while that which diffuses at the slow rate is probably concerned with exchanges between the plasma and such fluids as the vitreous body, aqueous humor, and cerebrospinal fluid. The regression curves observed suggest a possible third or slower rate of sodium diffusion such as might be expected for bone, dentin, and enamel already saturated with sodium.

The individual subjects in all groups showed a considerable spread in the blood and urine concentrations and rates of sodium cleared by the kidneys. The patients with congestive heart failure with treatment, including dietary restriction of sodium, showed a more rapid rate of sodium diffusion from the vascular bed than did the normal subjects. This was also true for a patient with phlebothrombosis receiving only bed rest therapeutically. The rate of turnover of the interstitial fluid sodium was 50 per cent as rapid in the patients with congestive heart failure as in the normal subject, while the plasma sodium of the patients with congestive heart failure turned over twice as rapidly as that of the normal subject.

The rapid rates of diffusion and the large quantities of sodium involved make it necessary to reconsider the role of sodium in edema formation. Relatively slight changes in the rates of sodium diffusion from the blood with a disturbance in its excretion in the urine might result in rapid and marked edema formation.

The rate of sodium clearance in the patients with congestive heart failure was considerably less than that in the normal subjects. These differences were not due entirely to a dietary restriction of sodium intake.

Simultaneous study of each kidney showed a tendency for the renal excretion of sodium to be similar bilaterally. There was sufficient qualitative and quantitative difference, however, to indicate intrinsic renal differences in the excretion of sodium. In some instances these differences were considerable.

The important technical assistance of Miss Shirley Wiederecht, Miss Jacquelyn Souderes, Miss Elsie Landry, Mr. F. M. Parks, Mr. R. J. Schramel, and Mr. G. J. Fruthaler is gratefully acknowledged.

It was through the interest and kindness of Dr. A. L. Hughes and Dr. Martin Kamen of Washington University, and of Dr. Allen Reid and Mrs. Adele Weil, of Columbia University, that the radiosodium was made available for these studies.

MANNITOL: KINETICS OF DISTRIBUTION, EXCRETION, AND UTILIZATION IN HUMAN BEINGS

RAFAEL DOMINGUEZ, M.D., A. C. CORCORAN, M.D., AND
IRVINE H. PAGE, M.D.
CLEVELAND, OHIO

MANNITOL is in current clinical use as a measure of the rate of glomerular filtration¹⁴ and of the volume of extracellular fluid.¹¹ It is also recommended as a harmless osmotic diuretic.

The availability of a method⁴ for the determination of plasma mannitol, which, especially at low concentrations, is more precise than procedures formerly in use, enabled a study of the distribution, excretion, and utilization of mannitol after intravenous injection in human beings. This study is based on concepts previously developed⁵⁻⁸ and applied to creatinine, xylose, and galactose. Since these concepts have been presented in detail and verified experimentally, we limit our prefatory discussion to general terms and to specific symbolisms used in this report.

If the rate of urinary excretion, y , of a substance (milligrams per minute) is proportional to the concentration, x , of this substance in plasma (milligrams per cubic centimeter), the excretion constant A can be calculated. This constant A is usually interpreted as the volume of plasma cleared of the substance per unit time and is called clearance (cubic centimeter per minute). It may be interpreted also as the rate of excretion per unit plasma concentration, or, in short, the specific rate of excretion. When the substance in question is disposed of wholly by renal excretion and when the rate of diffusion of this substance into body fluid is such that the amount lost before equilibration is negligible, the constant A can be calculated from serial determinations of the concentration of the substance in plasma. The calculation can be made graphically from a plot of plasma concentration x on semilogarithmic paper. This plot will follow a straight line with slope α . The initial concentration a is obtained directly by extrapolating the line to the time of injection. This value a corresponds to a theoretic concentration of the substance in the plasma under the assumption of mixing and equilibration at the time of injection. The dose, G , being known, the volume of distribution, V , of the substance is determined from G and a . The excretion constant A is obtained from G , a , and slope α . The formulas are collected for convenience in Table I, while Fig. 1 illustrates the procedure.

When the rate of equilibration is such that significant disposal of the substance takes place before equilibrium is established, the values V and A must be regarded only as first approximations, identified by a subscript 1, as A_1 and V_1 . If the pre-equilibrium plasma concentrations are known, as in the experiment shown in Fig. 1, the slope β and the extrapolated concentration b can be determined from the excess of plasma concentration above the line of the slope α .

Received for publication. July 25, 1947.

With these new constants a second approximation, A_2 , and a new V , V_2 , are then calculated (Table I). The value A_2 measures the total specific rate of disposal of the substance by urinary and other possible pathways and represents total plasma clearance.

Fig. 1.—Graphic solution of the equation of the plasma disappearance curve, $X = ae^{-\alpha t} + be^{-\beta t}$ (No. 77).

$$a = .355$$

$$\alpha = \frac{\ln 0.355 - \ln 0.10}{113.5} = \frac{1.2669}{113.5} = 0.01116$$

$$b = .285$$

$$\beta = \frac{\ln 0.285 - \ln 0.01}{29.6} = \frac{3.3499}{29.6} = 0.1131$$

The extraordinary pathways of disposal lie either in metabolism or extra-renal excretion. The sum of these processes is referred to herein and in earlier reports as utilization. If the substance (1) is both excreted in the urine and utilized and (2) disappears exponentially from plasma, the former value A_1 must be regarded as the sum of two constants, A_s and B_s , of which A_s is another approximation to the renal plasma clearance and B_s is the utilization constant. This constant represents the rate of utilization per unit plasma concentration, or, in brief, the specific rate of utilization.

The value of A_s is calculated from the amount, E , of the substance which appears in the urine. When the time of urine collection is prolonged and renal function intact, so that excretion is virtually complete in the time of collection, A_s is calculated as shown in Table I. When the period of collection is short, so that excretion is incomplete, an exponential term is introduced leading to the value A_s' (Table I).

TABLE I. FORMULAS USED IN THIS REPORT

(1) $y = \Delta x$	(2) $\int y \, dt = \Delta \int x \, dt$
(3) $x = ae^{-\alpha t} + be^{-\beta t}$	(4) $\Delta_1 = \frac{\int y \, dt}{\int x \, dt} = \frac{G}{\int ae^{-\alpha t} \, dt} = \left(\frac{a}{\alpha} \right)$
(5) $\Delta_2 = \frac{G}{\int (ae^{-\alpha t} + be^{-\beta t}) \, dt} = \frac{G}{\frac{a}{\alpha} + \frac{b}{\beta}}$	
(6) $\Delta_2 = \frac{E}{\frac{a}{\alpha}}$	(7) $\Delta_1 = \frac{E}{\frac{a}{\alpha} + \frac{b}{\beta}}$
(8) $\Delta_1' = \frac{E_t}{\frac{a}{\alpha} (1 - e^{-\alpha t})}$	(9) $\Delta_1' = \frac{E_t}{\frac{a}{\alpha} (1 - e^{-\alpha t}) + \frac{b}{\beta} (1 - e^{-\beta t})}$
(10) $\frac{\Delta_2}{\Delta_1} = \frac{\Delta_1}{\Delta_2} = \frac{E}{G}$	(11) $B_1 = \Delta_2 - \Delta_1$
(12) $V_1 = \frac{\Delta_1}{\alpha}$	(13) $V_2 = \frac{\Delta_2 (\beta^2 a + a^2 b)}{(\beta a + \alpha b)^2}$
(14) $\frac{\Delta_1}{\Delta_2} = 1 + \frac{\alpha}{\beta} \cdot \frac{b}{a}$	(15) $\frac{V_1}{V_2} = 1 + 2 \frac{\alpha}{\beta} \cdot \frac{b}{a}$ approximately

The formulas used herein and in earlier reports are summarized in this table for convenience. The meanings of the symbols are explained in the text.

G, Quantity injected in milligrams.

E, Total urinary excretion, milligrams.

E_t, Quantity excreted in urine in time, t.

In the calculations of Δ_1 and Δ_1' , the diffusion of the substance is neglected. If both diffusion and extraurinary disposal are taken into consideration, a value, Δ_4 (and also Δ_4' for a short period of collection), can be calculated as shown in Table I. The value Δ_4 is equal to renal plasma clearance of a substance which is excreted in urine and which is also utilized and subject to pre-equilibration disposal.

Successive calculations of these different values of Δ give explicitly the errors introduced in the estimate of renal clearance. The ratio $\frac{\Delta_1}{\Delta_2}$ gives the relative error introduced in the estimate Δ_1 by neglecting diffusion. The ratios $\frac{\Delta_1}{\Delta_3} = \frac{\Delta_2}{\Delta_4}$ give the relative error introduced in the estimates Δ_1 and Δ_2 by assuming no utilization. The ratio $\frac{\Delta_1}{\Delta_4}$ gives the relative error introduced in the estimate Δ_1 by neglecting diffusion and by assuming no utilization.

The utilization constant B already defined is obtained from the difference $(\Delta_2 - \Delta_4)$ (Table I).

PROCEDURE

Seventy experiments were performed on fifty-six subjects, thirty-nine of whom suffered from some form of renal disease. Twenty cubic centimeters of a

25.5 per cent solution of mannitol* were rapidly injected intravenously. Plasma samples were obtained after equilibration in some experiments and both before and after equilibration in other experiments. The number of plasma samples varied from three to seven. Urine was collected for short periods (averaging 105 minutes) and for long periods (nine to twelve hours). The distribution of procedures is shown in Table II.

TABLE II

PLASMA SAMPLING	URINE COLLECTION			TOTALS
	NONE	SHORT	LONG	
After equilibration	36	13	7	56
Before and after equilibration	2	7	5	14
Total	38	20	12	70

Data from one of the five experiments with long urine collections in which plasma was obtained before and after equilibrations are shown in Fig. 1, from which the course of other experiments can be visualized. In each of ten subjects the experiments were repeated once, and in each of two other subjects the experiments were done three times. Two of the repeated experiments cannot be averaged because of changes in the subject's renal excretory function.

Plasma mannitol clearance, C , was determined in patients independently of this procedure on thirty occasions (Table IV). These determinations were done by the conventional method of intravenous infusion, plasma sampling, and urine collection by catheterization and by bladder washing. A value termed C' was calculated from the curve of plasma concentrations and concurrent excretion of mannitol in voided urine in five experiments. This value is equivalent to conventional clearance determination, but, in contrast with C in this series, the determination C' is simultaneous with the experiment rather than an independent observation.

RESULTS

Volume of Distribution.—Mean V_i in the whole group is 14.2 liters, while mean body weight, W , is 66.7 kilograms, mean surface area, S , is 1.74 square meters, and mean developmental level, $D.L.$,¹⁶ is 166. The correlation coefficient between V_i and W is 0.49; that between V_i and S , 0.53; and between V_i and $D.L.$, 0.53. The relation between V_i and $D.L.$ is shown in Fig. 2, which demonstrates that, on an average, V_i is greater in patients than in normal subjects at equal developmental levels. The differences in the means of V_i between patients (14.9 liters) and normal subjects (12.6 liters) is 2.3 liters, which is found to be 2.8 times the standard error of the difference and is, therefore, significant. The importance of the difference is still more apparent when it is related to body weight or developmental level in the two groups, mean W being 65.9 kilograms in patients and 68.8 kilograms in the normal group and mean $D.L.$ being, respectively, 164 and 170.

*We acknowledge the generosity and interest of Dr. Carl Beyer and Dr. William Boger, of Sharp & Dohme, Inc., Philadelphia, Pa., and the skillful assistance of Dr. L. Underwood and Miss E. Davy, R.N.

The second approximation of volume of distribution, V_2 , is calculable in those cases in which plasma mannitol was determined before equilibration. In this group V_1 averages 13.8 liters and V_2 , 12.3 liters (Table III). The difference is 1.5 liters and the ratio $V_1:V_2$ is 1.12. The excess of the ratio $V_1:V_2$ over unity measures the error in the estimate of volume of distribution occasioned by

Fig. 2.—Relation between V_1 and developmental level, $D.L.$, in patients and in normal subjects. The means for each group are indicated as X . These points are joined to zero by straight lines. The upper line indicates the relation of $V_1:D.L.$ in patients; the lower line, the relation in normal subjects; and the middle line, that in the whole group.

Constants obtained in experiments in which plasma mannitol concentrations were known before and after equilibration. The value P (Dominguez) is the volume into which injected mannitol diffuses so rapidly that it is identified in earlier reports as equivalent plasma volume. In these experiments the volume P averages about 2.7 times true plasma volume as estimated from body weight and 0.62 times the final volume of distribution, V_2 . The significance of the other constants is explained in the text.

neglecting diffusion prior to equilibration (Table I). V_2 is, therefore, the more exact measure of volume of distribution. If this value of $\frac{V_1}{V_2}$ holds for the whole group, V_2 averages 13.3 liters (20 per cent of body weight) in patients and 11.3 liters (16 per cent of the body weight) in normal subjects.

Equilibration of Mannitol in Body Fluid.—Since mannitol is subject to continuous disposal, the equilibration of mannitol in body fluids is dynamic. After a single injection, the first gradient is from plasma to interstitial fluid, and the second, from body fluid to plasma, from which mannitol is excreted in urine. The time of equilibration marks completion of the first phase, after which disappearance of mannitol from plasma becomes simply exponential. Plasma samples were obtained at or about twenty minutes after injection in thirty-nine subjects. The weighed mean time of equilibration is twenty-seven minutes, equilibrium being established at twenty minutes in nineteen experiments, at twenty-five in one, at thirty in ten, and at forty in nine. In four experiments in which the first blood sample was taken at thirty minutes, equilibration had already been established. The mean time of equilibration in the fifteen experiments in which blood samples were obtained shortly after injection (as in Fig. 1) was twenty-eight minutes, the times being twenty minutes in six, twenty-five minutes in one, thirty minutes in three, thirty-five minutes in four, and forty-five minutes in one.

Thus, mannitol was equilibrated in body fluids at a mean interval of twenty-seven to twenty-eight minutes after injection, but it is well to bear in mind that in ten of fifty-eight experiments the time of equilibration was forty minutes or more.

Renal Excretion.—The first approximation of the specific rate of mannitol disposal A_1 is compared with the independently determined renal plasma clearance, C , in Table IV. The ratio of the mean of A_1 and C in this group is 1.44. This estimate of the ratio $A_1:C$ may be somewhat affected by changes in function between measurements of A_1 and C . But the inequality of the means indicates that a considerable portion of injected mannitol is disposed of by avenues not taken into account in assuming the equivalence of A_1 and C in the estimation of A_1 . There must be loss before equilibration, or utilization before and after equilibration, or a combination of these factors.

That disposal before equilibration should not be as great as the excess over unity of $A_1:C$ indicates is suggested by the rapidity of mannitol diffusion. The effect of diffusion from plasma on the estimate of volume of distribution is noted in the foregoing in comparing V_1 and V_2 . Similarly, the effect of this diffusion on the estimate of specific disposal rate is observed in the ratio of mean $A_1:A_2$ (Table V) which is 1.08, an excess over unity of the same order as that of the ratio $V_1:V_2$. Loss of injected mannitol before equilibration is, therefore, not negligible.

However, if such loss were the only factor determining the excess of A_1 over C , the ratio A_2 to C' would be unity. Actually, the ratio of the means is 1.23 (Table V), from which it follows that the specific rate of disposal of injected mannitol involves also a considerable utilization of this substance.

TABLE IV. COMPARISON OF THE MANNITOL CLEARANCE C TO THE FIRST APPROXIMATION A_1 TO THIS CLEARANCE

C SMALLER THAN 70			C GREATER THAN 70		
NO.	A_1	C	NO.	A_1	C

62	94	50			
63	44	28			
64	77	50			
Mean	67.9	46.2		144.3	99.7

Mean $A_1 = 1.14 \times$ mean C in patients whose level of C is less than 70, and 1.15 when C is greater than 70. The mean of the ratios $A_1:C$ for patients is 1.62 when C is less than 70 ($S.D.$, 0.55) and 1.17 ($S.D.$, 0.23) when C is greater than 70. The difference between these means is not significant (difference/standard error of difference is less than 1). The greater variability of data in patients in whom C is less than 70 is attributed in part to changes in function which may have occurred in the interval between measurements of A_1 and C . Such changes are less marked when function is initially close to normal with C greater than 70.

TABLE V. SUCCESSIVE APPROXIMATIONS TO THE CLEARANCE OF MANNITOL COMPUTED FROM THE PLASMA CURVE ALONE (A_1 AND A_2), FROM THE PLASMA CURVE AND SHORT INTERVAL OF URINE COLLECTION (A_2' AND A_3') AND FROM THE PLASMA CURVE AND LONG INTERVAL OF URINE COLLECTION (A_3 AND A_4). 81	125	117		116		108	112	
Mean	145	134		122		112	109	

Data from patients (Nos 60 to 66) and normal subjects (Nos 77 to 81). Data from patients are not averaged because of their variability. The means of the ratios of A in normal subjects are as follows: $A_1:A_2$, 1.29; $A_2:A_2'$, 1.20; $A_2':A_3$, 1.08; $A_3:A_3'$, 1.03; $A_3':A_4$, 1.08; $A_4:A_1$, 1.19; $A_1:C$, 1.33. The specific rate of utilization B_1' in experiments with short periods of urine collection averages 34 and is widely variable. In normal subjects, with prolonged urine collection, mean $B_1 = 21$.

When this utilization is taken into account, as it is in calculating A_3 and A_3' , neglecting pre-equilibrium disposal, the means of these values only slightly exceed the means of C and C' (Table V) (ratio of mean $A_3:C'$ is 1.12). This excess over unity measures the degree to which the estimate of renal excretion of mannitol (A_3 or A_3') is affected by pre-equilibration disposal. When this loss is also accounted for, as it is in calculating A_4 and A_4' , the correspondence

of A_1 and A_1' with C and C' is seen to be close (Table V) (ratio of mean $A_1:C'$ is 1.03). The discordance of three ratios $A_1:C$ (Nos. 63, 65, and 66) can be attributed to changes in renal function which may have occurred in the interval between the determination of C and that of A_1 . This supposition is supported by the fact that the concordance with the simultaneous observations C' is nearly exact.

Thus, specific rate of renal mannitol excretion obtained from serial determinations of plasma mannitol as A_1 or A_1' corresponds with values for renal plasma mannitol clearance, measured as C or C' . Both utilization and diffusion must be taken into account in the estimation of renal mannitol clearance from serial analyses of plasma after injection of mannitol.

Utilization.—The difference (A_1-A_1') establishes the existence of mannitol utilization and measures the specific rate of this utilization, B . Direct evidence of this extraordinary disposal is obtained (Table VI) from observation of urinary excretion of mannitol over a long interval of time in subjects with normal or nearly normal renal functions. The mean recovery of injected mannitol is 79 per cent. Recoveries of 81 and 89 per cent were obtained by Smith, Finklestein, and Smith¹⁴ in ten and one-half hours of urine collection, and recoveries of 80, 85, and 90 per cent in twenty-four hours by Berger, Farber, and Earle.²

TABLE VI. RECOVERY OF MANNITOL IN THE URINE; 5,100 MG. INJECTED

SUBJECT	TIME (MIN.)	AMOUNT OF MANNITOL (MG.)	PER CENT RECOVERED
70	720	3,595	70.5
71	720	4,329	84.9

79	785	4,350	85.3
80	540	4,411	86.5
81	720	4,702	92.2
Mean	680.4		79.04

The validity of a nine- to twelve-hour urine collection as a measure of total urinary excretion can be shown by the following example (No. 77). The value of a is found as 0.355 mg. per cubic centimeter; α , .0112; b , .285; β , 113; t , 540 minutes; αt , 6.048; βt , 61.02; and $1-e^{-6.048}$, .99764. Amount excreted in 540 minutes is 4,331 milligrams. Assuming the 540 minute excretion to be total excretion, E , 4,331 = A_1 (34.22) and $A_1 = 126.6$ cubic centimeters per minute. Taking now 4,331 only as the amount excreted, E_t , in 540 minutes, and calculating A_1' , as is done when urinary excretion is incomplete, we have $4,331 = A_1'$ ($31.70 \times .99764 + 2.52$) from which $A_1' = \frac{4331}{34.15} = 126.8$ cubic centimeters per minute. The correspondence of A_1 and A_1' shows that excretion in 540 minutes is a close measure of total excretion. Actually, with $A_1' = 126.8$, the total cal-

culated excretion will be $126.8 \times 34.22 = 4,339$ milligrams. The difference between this and the amount excreted in 540 minutes is only 8 mg., or 0.2 per cent of E .

Indeed, when αt is greater than 4.667, the factors $1-e^{-\alpha t}$ and $1-e^{-\beta t}$ can be neglected, being less than 1 per cent of unity. As a matter of fact, the smallest value of αt in the experiments of Table VI is 5.83. Consequently, the amounts excreted in the experiments of Table VI are less than 1 per cent smaller than the total excretion, and the mean recovery of 79 per cent can be considered equal to total recovery of injected mannitol.

The specific rate of mannitol utilization is measured as B . In experiments of short duration, this constant is estimated as 34, mean of B_1' , and in experiments with long urine collection, as 21, mean of B_2 (Table V). The greater variability of data in the shorter experiments leads us to believe that the estimate of B from the longer experiments (B_2) is the more representative of the specific rate of mannitol utilization in human beings.*

DISCUSSION

The present investigation was aimed at evaluating renal function by the disappearance of intravenously injected mannitol from plasma without collection of urine in the manner suggested by Barnett¹ for inulin and by Newman, Bordley, and Winternitz¹¹ for mannitol.

In proposing this procedure as a measure of glomerular filtration, the latter authors note that it is based on the assumptions, "(1) that mannitol is dissolved in a space approximating the extracellular fluid of the body; (2) that an equilibrium of concentration is established throughout the fluid; and (3) that loss of mannitol is only through excretion by the kidneys." The first of these assumptions is supported by our data, since the volume V_2 corresponds well with other estimates of extracellular fluid volume. The third assumption is negated by the demonstrated utilization of mannitol. The view implicit in the second assumption that excretion of mannitol before equilibration is negligible is also controverted, since neglect of this disposal introduces errors of about 10 per cent in the estimates of V and Δ . It is, therefore, impossible to arrive at an accurate estimate of renal plasma mannitol clearance when only the dose injected, G , and the slope, α , are known. It has recently been shown^{2, 4, 10, 13} that the plasma clearance of mannitol is about 90 per cent of that of substances presumably excreted by glomerular filtration without tubular reabsorption.

However, with the additional safeguards⁶ of a knowledge of pre-equilibrium plasma concentrations and of the amount excreted, renal plasma mannitol clearance can be calculated as Δ_1 or Δ_1' . Unfortunately for convenience the procedure then requires at least four and preferably five plasma samples, and, because of the individual variability of the specific utilization constant B , a prolonged collection of urine.

*The ratio of the clearance determined by the infusion method of Earle and Berliner⁹ to conventional plasma mannitol clearance is found by Berger, Farber, and Earle² to be 1.12. If renal plasma mannitol clearance of these subjects is taken as 110, the specific rate of utilization is $(110 \times 1.12 - 110) \approx 13$.

The behavior of intravenously injected mannitol in human beings resembles that of xylose in dogs.⁹ Like xylose, mannitol is distributed in a comparable volume of body fluid, is largely excreted in the urine by glomerular filtration and slight reabsorption,¹² and is also subject to utilization. On the basis of body weight, the utilization constant B of mannitol in normal human beings is 0.30, while that of xylose in dogs is 0.97. This difference in the constants emphasizes the value of the calculation of B in estimating utilization. The mean per cent recovery of xylose in dogs averages 60 per cent and that of mannitol in human beings, 80 per cent, from which it appears that the two substances are utilized in comparable proportion. However, the specific rate of utilization of xylose per unit body weight is three times that of mannitol.

It is interesting to note that in dogs the specific rate of utilization of sorbitol, the isomer of mannitol, is even greater than that of xylose. If we assume a body weight of 15 kilograms and an A of 35 in the experiments of Todd, Myers, and West,¹³ the estimate³ of B for sorbitol is 3.5 per kilogram of body weight.

The pathway of utilization of mannitol is unknown. It seems unlikely that mannitol should be subject to significant extrarenal excretion; therefore, utilization of mannitol, like that of xylose, may be taken as due to metabolic conversion.

Most published studies on the metabolism of mannitol are based on feeding experiments. These studies have shown that, in the rat, ingestion of mannitol leads to storage of liver glycogen.^{3, 15} In the rabbit, mannitol does not relieve the symptoms of insulin shock.³ Since mannitol is readily subject to bacterial degradation, it has been assumed that most of the metabolic utilization of ingested mannitol is due to absorption of products of bacterial action. However, the comparatively rapid utilization of mannitol we describe suggests that the results of feeding experiments reflect parenteral conversion rather than enteral breakdown.

SUMMARY AND CONCLUSIONS

The disposal of a single intravenous injection of mannitol in human beings is described on the basis of concepts formerly applied to creatinine, xylose, and galactose. The method of calculation is presented.

The volume of distribution of mannitol in body fluids is estimated as 16 per cent of body weight in normal subjects and 20 per cent in patients suffering from cardiac and renal disease. When no allowance is made for disposal of mannitol before equilibration in body fluids, the estimates of distribution volume are increased by 12 per cent. The time of equilibration of mannitol in body fluids averages 27.5 minutes, but in ten of fifty-eight experiments this interval was prolonged to forty minutes or more.

Utilization of mannitol, presumably metabolic, is shown to proceed at a rate which, like the specific rate of excretion, can be expressed as a specific rate of utilization in milligrams per minute per unit plasma concentration. This specific rate is estimated as about 21 in normal human beings. In subjects with normal renal function, excretion of injected mannitol is completed

in nine to twelve hours. The proportion excreted in this time averages 79 per cent of the amount injected.

The estimate of renal plasma mannitol clearance from the exponential plasma disappearance curve and the dose alone after a single intravenous injection is inadequate. In normal subjects the error is found to be about 30 per cent when no allowance is made for pre-equilibration disposal and for utilization. The error is reduced to 20 per cent by taking into account pre-equilibrium disposal, and to about 10 per cent when allowance is made for utilization. Although variability of data is considerable in patients suffering from diseases which alter renal function, the mean error of the estimate of mannitol clearance from the plasma disappearance curve is negligible when allowances are made for both utilization and pre-equilibration disposal. In practice, this estimate requires analysis of serially obtained plasma samples and of urine collected over a long interval.

STUDIES IN SERUM PROTEINS

I. THE CHEMICAL ESTIMATION OF ALBUMIN AND OF THE GLOBULIN FRACTIONS IN SERUM

CLARENCE COHN, M.D.,* AND WILLIAM QUITMAN WOLFSON, M.D.†
CHICAGO, ILL.

THE increasing clinical significance being attached to the various components of the serum proteins as revealed by electrophoresis necessitates a simple, rapid procedure for estimating these fractions. The characteristics of the Tiselius electrophoresis apparatus make it impractical for most clinical laboratories. As a result, fractionation studies cannot be performed in many cases where they would be desirable.

A simple chemical fractionation method which approximated the results obtained by electrophoresis is reported. This chemical procedure requires no special equipment and can be performed in several hours of actual working time using serum samples of nominal size.

MATERIALS AND METHODS

Four human sera, one normal and three abnormal, were fractionated by both electrophoretic and chemical methods. Five samples of animal plasma were also studied; these were obtained as desiccated powders and were reconstituted with distilled water. In the case of the animal plasma samples it was necessary to undertake a preliminary removal of fibrinogen; this was done by the addition of purified clotting thrombin. Three of the animal samples were of sheep plasma, and one each of equine and porcine plasma.

Analyses‡ on the human sera and on the animal plasma samples were carried out electrophoretically; in calculating the percentage composition of the fractions of these samples (Table II) a suitable correction has been made for fibrinogen.

Chemical procedures utilized for determining the various protein fractions were as follows:

1. Total protein was determined by the biuret reaction as modified by Weichselbaum.¹

*Director, Department of Biochemistry, Michael Reese Hospital.

†Assistant to the Director, Department of Biochemistry, Michael Reese Hospital.

‡Analyses on human sera carried out by Dr. Donald Buchanan; those on animal plasma samples, by Dr. J. D. Perrings.

We are greatly indebted to Dr. C. C. Barron and Dr. Donald Buchanan, of the Department of Medicine, University of Chicago, for their kind cooperation in making it possible to check our human sera analyses runs, and to Dr. R. L. Kutz and Dr. J. D. Perrings of the Biochemical Laboratories, Armour and Company, who provided us with liberal samples of desiccated animal plasma of precisely known electrophoretic composition.

2. Albumin plus alpha globulin is equivalent to the "albumin" fraction obtained by employing Kingsley's modification of Howe's method to precipitate "globulin."² The estimation was finally performed by the biuret method.
3. Albumin values were obtained by the methanol fractionation procedure of Pillemer and Hutchinson.³ The methanol filtrate was analyzed for protein by the biuret reaction.
4. Gamma globulin was separated from serum by a modification of the method of Cohn and co-workers.⁴ A solution of the precipitating reagent was prepared by adding 2.5 ml. of 1 N. sulfuric acid to 100 ml. of 2.78 M. ammonium sulfate. Five-tenths milliliter of serum was placed in a graduated 10 ml. Kolmer centrifuge tube. Four milliliters of precipitating solution were then placed in a doubly tied cellophane bag suspended in the tube and centrifuged until 0.5 ml. of ammonium sulfate solution had been added to the serum. The rate of centrifugation was adjusted so that about two hours were required. The cellophane bag was then removed. After standing overnight, the tube was again centrifuged until the precipitate was well packed. The supernatant was discarded and the precipitate taken up in 0.9 per cent NaCl solution. The protein concentration, consisting almost entirely of gamma globulin,⁴ was estimated by the turbidometric method of Ayer, Dailey, and Fremont-Smith.⁵

Care should be taken to approximate the end point as closely as possible. However, the end point should be passed slightly, an amount of serum exactly equal to the excess of ammonium sulfate added should be pipetted into the centrifuge tube. The serum added is then mixed well with the supernatant and the tube warmed to 35 to 40° C. for thirty minutes, following which it is permitted to stand overnight and treated in the usual fashion.

5. The value for beta plus gamma globulin was obtained by subtracting the value for albumin plus alpha globulin from total protein values (Step 1 minus Step 2).
6. Beta globulin was estimated by subtracting the value obtained for gamma globulin (Step 4) from the value obtained for beta plus gamma globulin (Step 5).
7. Alpha globulin concentration was obtained by subtracting the value for albumin (Step 3) from that of albumin plus alpha globulin (Step 2).

These determinations can be accomplished in three hours of actual work. However, since the gamma globulin precipitation requires standing overnight twelve to eighteen hours are needed from the time the samples are received. It is preferable that the determinations be carried out in duplicate. For the complete analyses in duplicate 6.5 ml. of serum are required.

RESULTS AND DISCUSSION

A consideration of the method outlined will show that its operation fundamentally depends upon the assumption that the "albumin" found by the Howe method of sodium sulfate precipitation actually is equivalent to the electro-

phoretically determined true albumin plus alpha globulin, and that the "globulin" of the Howe method actually is equivalent to beta plus gamma globulin. This assumption was originally based upon a review of the older papers in which sodium sulfate and electrophoretic fractionation were compared.^{6,7} While the present study was in progress, Petermann, Young, Hoagness, and Rhoads⁸ also observed the coincidence in values between the Howe "albumin," on one hand, and the sum of the electrophoretic values for albumin and alpha globulin on the other.

The data obtained in the course of this study appear to justify this assumption. Table I lists the values obtained for various serum components by the chemical and the electrophoretic method in human subjects. In both Table I and Table II good correspondence is shown between the Howe "albumin" (albumin plus alpha globulin obtained by the chemical method) and the electrophoretic values for albumin plus alpha globulin.

No difficulty was encountered in obtaining duplicate checks of the values for total protein, albumin plus alpha globulin, beta plus gamma globulin, and gamma globulin. However, we agree with Petermann and co-workers⁸ in emphasizing that to obtain reliable and reproducible results for albumin, the most meticulous care must be used in the preparation of the reagents, in avoiding evaporation, and in maintaining all components of the system at 0° C. throughout the precipitation and filtration process. Because of the delicacy of the Pillemer and Hutchinson method,³ consideration is being given to the possibility of substituting the albumin method suggested by Chow⁹ which he has shown also to give values for albumin which approximate electrophoretic values.

In Table II we have compared all average values obtained by the chemical method with those obtained by electrophoresis. It can be seen that the average difference between the two methods does not exceed 10 per cent for any fraction. Electrophoretic values depend on the particular buffer used and some fractions may vary as much as 60 per cent in successive determinations on the same sample with different buffers. The agreement between the electrophoretic and precipitation methods appears to be satisfactory.

The agreement between individual electrophoretic and chemical results^{*} was somewhat poorer for the animal sera than for the human. It appears likely that this resulted from the necessity of removing fibrinogen by the use of clotting thrombin before the samples could be analyzed.¹⁰

In addition to its general availability, the chemical method has one advantage not shared by the Tiselius procedure. Since the biuret method employed for the individual determinations estimated protein alone, other substances of lipid or carbohydrate nature which migrate with protein fractions are not measured. In the Tiselius apparatus, values for such protein-bound substances are included in calculating the percentage composition of the various fractions. On the other hand, the Tiselius method provides a direct check on the purity of the individual fractions in the schlieren diagram; and it also permits determination of subfractions of the major globulin fractions.

*We have been requested to withhold individual electrophoretic analyses of the animal samples as these form a portion of studies to be published separately.

TABLE I. COMPARISON OF PROTEIN FRACTIONATION VALUES OBTAINED BY ELECTROPHORESIS AND CHEMICAL PRECIPITATION IN HUMAN SERA

SERUM	DIAGNOSIS	FRACTIONATION METHOD	TOTAL PROTEIN (GM. %)	ALBUMIN (GM. %)	GLOBULIN (GM. %)

TABLE II. COMPARISON OF PROTEIN FRACTIONATION BY CHEMICAL AND ELECTROPHORETIC METHODS*

SERA	ALBUMIN	ALBUMIN PLUS		ALPHA GLOBULIN	BETA PLUS		GAMMA GLOBULIN
		ALPHA GLOBULIN	GLOBULIN		GAMMA GLOBULIN	GLOBULIN	
Human†	0.97	1.01	1.02	1.02	1.03	1.03	1.03
Farm animals‡	0.95	0.98	1.07	1.07	1.08	1.10	1.05

*The results are expressed as the ratio of the protein fraction obtained by chemical methods to the protein fraction by electrophoresis.

†Results from one normal and three abnormal sera.

‡Results from three sheep, one horse, and one porcine sera.

SUMMARY AND CONCLUSION

A precipitation method for the fractionation of sera is described. This method gives values for albumin and alpha, beta, and gamma globulin which show good agreement with those obtained by electrophoretic analyses.

SODIUM AND POTASSIUM DETERMINATIONS IN HEALTH AND DISEASE

T. P. MARINIS, M.D., E. E. MURHEAD, M.D., FRANCES JONES, B.S., M.T.,
AND J. M. HILL, M.D.
DALLAS, TEXAS

THE data in this report will be presented in three segments: (1) the concentration of sodium and potassium in the sera of 107 normal adults, (2) the results of various recovery experiments, and (3) several cases demonstrating the clinical application of sodium and potassium determinations. The flame photometer^{1, 2} offered a rapid means of accurately determining the concentrations of these ions.

APPARATUS

The flame photometer used in these observations was the Perkin-Elmer instrument, Model 18. The recommended technique was followed.² The burner was fed natural gas from the city mains via the recommended constant pressure adjustment. The air pressure leading to the atomizer was maintained at 14 pounds. Two adjustments were necessary in relation to these features of the instrument before constant reproducible readings were obtained. By trial and error method the aperture of the jet giving the most constant readings was found to be 0.8 millimeter. This 0.8 mm. aperture was made by soldering a thin sheet of brass over the opening of the larger jet supplied and gradually reaming out a hole that would produce a flame of maximum heat without "feathering" (that is, loss of the small blue cones above the burner grill). Second, a moisture trap was placed in the air pressure line to keep chemically contaminated moisture away from the flame.

It is understood that improved instruments which circumvent these difficulties will be available in the future.³

NORMAL SERUM SODIUM AND POTASSIUM VALUES

Serum Na and K concentrations were determined on 107 normal, ambulatory adults (blood donors). Most of these subjects had been at rest more than twenty minutes prior to the collection of samples. The samples were taken at the end of the blood collections in the blood bank and consisted of the last column of blood in the collecting tube. This blood was allowed to drain by gravity into a test tube after withdrawal of the needle from the vacuum bottle. Test tubes previously were rinsed scrupulously with sodium- and potassium-free distilled water. The clot was allowed to contract and the serum was obtained by centrifuging.

The actual analysis for sodium or potassium was simple. For Na, the serum was diluted 1:100 with distilled water. The instrument was set at zero

From Clinical Pathology Department, Baylor Hospital.
Received for publication, July 1, 1947.

with the same distilled water and at 100 with a standard sodium solution. The standard used contained 50 ppm of sodium in the form of pure NaCl. The sodium concentration was obtained by the equation $C_u = \frac{C_s R_u}{R_s} \times 100$ where C_u is the concentration of the unknown, C_s the concentration of the standard, R_u the reading of the unknown, and R_s the reading of the standard. The equation is based on a linear relationship of dilutions of the 50 ppm standard with the instrument used (see Table VI). The K concentration determination was similar. The serum was diluted 1:10 with distilled water. The standard KCl solution contained 100 ppm of K.

Fig. 1.—Mean, 141.0 meq. per liter; standard deviation, 3.6 meq. per liter.

Fig. 2.—Mean, 4.52 meq. per liter; standard deviation, .45 meq. per liter.

Tables I and II contain the frequency distribution for the sodium and potassium determinations respectively. For the serum sodium values the following figures in milliequivalents per liter were determined: range 135.5 to

153.2; mean 144.0; standard deviation (σ) 3.6; coefficient of variation, 2.5 per cent. The potassium values in milliequivalent per liter were: range 3.6 \times 6.2; mean 4.52; standard deviation 0.45; coefficient of variation 9.9 per cent. For comparison Table III shows the normal ranges as reported by other methods.

STANDARDIZATION OF ANALYTICAL PROCEDURES

Table IV contains data on estimations of sodium concentrations. Sixteen separate samples of serum from normal adults were divided into four groups

of four each. The following amounts of sodium in milliequivalent per liter were added: 2.17 to the first group, 10.85 to the second, 21.7 to the third, and 43.4 to the fourth. The fourth column in the table gives the expected theoretic amounts to be recovered, and the fifth column gives the actual quantities determined by the flame photometer. The deviations observed are given in Column six.

TABLE IV. RECOVERY OF SODIUM ADDED TO NORMAL HUMAN SERUM

SAMPLE	ORIGINAL VALUE (MEQ./L.)	NA ADDED (MEQ./L.)	THEORETIC NA CON- CENTRATION (MEQ./L.)	RECOVERY VALUE (MEQ./L.)	DEVIATION (MEQ./L.)

16	4.70	11.52	16.22	16.10	-0.12

Table V has identical information concerning the sixteen samples with reference to the potassium concentration in milliequivalent per liter.

The deviations observed in these determinations are considered to be within the variations of standard clinical laboratory tests and indicate a satisfactory clinical applicability of the procedure.

In the next group of observations variations in the concentration of the standard solutions were made and recovery was tested. With Na (Table VI)

a standard of 50 ppm was used. The instrument was set at 100 with this solution and dilutions of the solution were tested for recovery. Three different groups were tested. Table VII has the same type of information with K standard solutions containing 100 parts per million. The observations in these groups indicate a degree of recovery which is quite satisfactory for clinical use.

	10	10.1	10.1	0.1

The influence of the dilution of the serum on the concentration values was tested for Na and is related in Table VIII. Greater variations were observed in this group of observations than in the former group. The 1:100 dilution seemed preferable because of higher and more stable readings.

TABLE VIII. EFFECT OF DILUTION OF SERUM ON THE PROPORTIONALITY OF PHOTOMETER READINGS TO CONCENTRATIONS OF SODIUM

Next, duplicate samples were tested for their potassium concentration. The results, given in Table IX, were quite satisfactory.

CLINICAL APPLICATION

The pertinent features of several cases are presented as illustrations of the applicability of this procedure to routine clinical use.

Case 1—The patient was D negative (Rh negative) and had been immunized to the D antigen by two pregnancies. After the second delivery she received 350 c.c. of D positive blood. A severe hemolytic reaction occurred and was followed by severe renal insufficiency (oliguria, heme casts, azotemia, hypertension, etc.). Hyponatremia developed but was prevented from becoming extreme by NaHCO_3 therapy. The K concentration was elevated at first but dropped to normal levels later. Table X contains the data related to Na and K.

The average NaHCO_3 intake per day prior to the diuresis was 4 grams. During the diuresis attempts were made to replace the Na and K lost on a gram per gram basis.

Case 2—The patient experienced extreme post partum bleeding which necessitated a hysterectomy. Hypotension existed for fifty one hours and was followed by renal insufficiency. A "force fluids" regime led to water intoxication. When seven eight days after the hypotension an alarmingly high serum potassium concentration was observed. Twenty grams of NaHCO_3 were quickly given by stomach tube, followed by 130 c.c. of 5 per cent NaCl solution by vein in two doses. The K value receded from the danger level and the Na concentration was elevated. Table XI presents data on this case.

noses* were (1) extracellular volume deficit with alkalosis and relative water excess and (2) relatively severe potassium deficit. The K values are shown in Table XII.

Case 1.—This was a case of fluid imbalance following a partial gastrectomy with Polya-Balfour anastomosis. On the seventh post-operative day a diagnosis of extracellular fluid deficit with a relative water excess was made by the surgical staff. Frequent serum Na and K determinations along with the clinical signs facilitated the handling of this case with hypertonic NaCl solution. The data are shown in Table XIII.

Case 5.—This case was one of chronic pyloric obstruction secondary to duodenal ulcer. There were Na and K determinations of the serum, gastric contents, and urine. There was a persistently low serum K concentration without any clinical signs of K deficit. After three weeks a gastroenterostomy was performed; recovery was uneventful. Table XIV presents the data.

*Made by Dr. Moyer.

Case 6.—A patient with Addison's disease was studied during the terminal crisis. The values of K and Na during the last three days are shown in Table XV.

Case 7.—A patient with adenocarcinoma of the stomach was studied during the post-operative period. The normal values obtained are shown in Table XVI.

SUMMARY

1. A series of observations of the concentration of Na and K in body fluids has been made using the flame photometer technique.
2. Determination of sodium and potassium in the blood sera of 107 normal blood donors was made. The average for sodium was 144.0 meq. per liter, with a range of 135.5 to 153.2 meq. per liter. The average for potassium was 4.52 meq. per liter, with a range of 3.6 to 6.2 meq. per liter.
3. Recovery experiments, duplicate determinations, and distribution curves of normal values indicate satisfactory accuracy for clinical use.
4. The presence of sodium, and also potassium, in the blood sera of several patients with various diseases was determined.

CHANGES IN THE BONE MARROW IN MEGALOBLASTIC ANEMIAS OF INFANCY BEFORE AND AFTER FOLIC ACID THERAPY

WOLF W. ZULLER, M.D., ANNE NEWHALL, M.D., AND LUCILE HUTAFF, M.D.
DETROIT, MICH.

UNDER the term megaloblastic anemia of infancy we have previously described an anemia characterized by changes in the blood and bone marrow resembling those of Addisonian pernicious anemia and by a specific response to folic acid.¹⁻³ The present report deals with the results of serial studies of the bone marrow which were undertaken in patients with this type of anemia for the purpose of elucidating the mechanisms underlying the development of the megaloblastic dysplasia and its disappearance under specific therapy.

MATERIAL AND METHODS

Our material consisted of fifteen patients* with megaloblastic anemia observed during a period of twenty one months at the Children's Hospital of Michigan. All the patients were white infants ranging in age from five weeks to one year. The clinical features were not characteristic. Usually there were signs of infection, and in three instances scurvy was noted. Eleven of the fifteen patients had histamine resistant achlorhydria at the time therapy was begun. Macrocytic anemia of varying degree was present in all cases. The hemoglobin levels on admission ranged from 1.7 to 8.3 Gm. per 100 c.c. (Table I). The percentage of reticulocytes was variable and in some instances moderately elevated even before therapy. Prior to folic acid therapy six patients received transfusions of whole blood and two others, transfusions of saline suspended washed red cells. Folic acid was administered by intramuscular injection in all but two instances, the daily dosage varying from 10 to 100 mg. and the total dosage, from 50 to 900 milligrams. The average course of treatment consisted of two daily injections of 10 mg. over a period of one week. To two patients folic acid (*Lactobacillus casei* factor) was given by mouth in daily doses of 5 mg. for ten day periods. Since it was evident that there was no appreciable difference in the response between patients receiving lower and higher dosage within the range given, no further reference to dosage will be made. In every case a characteristic increase in reticulocytes, up to 23 per cent, took place around the fifth day after the start of therapy, regardless of the initial degree of reticulocytosis, and hemoglobin and red cell counts rose significantly.

Daily complete blood counts and reticulocyte counts were made. Bone marrow was aspirated from the femur, and occasionally from the upper end of the tibia. In each instance at least one marrow sample before and after treatment was taken and in some instances as many as six serial examinations were made. A measured amount of marrow was withdrawn, usually between 1.0 and 2.0 c.c., although occasionally more or less marrow was accidentally obtained. The samples were placed in paraffin tubes containing heparin. One cubic centimeter was transferred into a Wintrobe tube, centrifuged for five minutes at 3,000 r.p.m., and the height of the various layers was recorded. The myeloid erythroid

‡Not examined.

layer was then thoroughly mixed on a paraffin-coated watchglass and films made from it were stained with May-Gruenwald-Giemsa. In each case a differential count of at least 500 nucleated cells was made, using the nomenclature of Downey⁴ and Jones.⁵ In addition, a count of 500 erythroblasts was made for each aspiration in eleven instances and in eight of these 100 mitoses in erythroblasts were classified for every sample.

QUALITATIVE CHANGES

Changes Before Therapy.—In six of the fifteen patients erythropoiesis was frankly megaloblastic.* As a rule the proportion of basophilic cells was high. This "shift to the left" in the maturation curve of the erythroid cells was paralleled by a relative increase in the number of mitoses encountered in basophilic cells. In examining many fields the total number of mitoses rarely appeared significantly increased and in some instances was clearly depressed, but actual counts were not made because the incidence of mitotic figures in only 500 cells would not have been significant. The mitotic figures were often distinctly pathologic. The chromosomes frequently appeared abnormally long and slender, the polarity of the mitotic spindle was often distorted, and aberrant chromosomes were common. Karyorrhexis and karyolysis were often pronounced. The granulocytes showed alterations in size, nuclear configuration, and cytoplasm indistinguishable from those seen in pernicious anemia.

In seven other patients classic megaloblasts were also present in fair numbers but did not constitute the majority of the erythroid cells. The predominant cell type, although closely resembling the megaloblast, failed to meet the strict criteria given by Jones⁵ and others, yet these erythroblasts were distinctly abnormal and different from normoblasts. In the course of our studies it soon became evident that the current nomenclature of marrow cells which implies two types of erythropoiesis was inadequate for our purpose. It would

*For illustrations see our earlier communication.²

have forced us to place pathologic cells in the category of normoblasts simply because they did not correspond in every detail to megaloblasts. We therefore temporarily adopted the term "intermediate" for erythroid cells which we could not otherwise classify. We do not wish to imply that these cells represent a separate type of erythropoiesis but merely to indicate that *morphologically* they occupy a middle position between typical normoblasts and typical megaloblasts.

The cells of the intermediate type were large, usually as large as megaloblasts and always significantly larger than normoblasts. The ratio of cytoplasm to nucleus was often increased. The nucleus had an increased amount of acidophilic matter and the chromatin net was much finer and more regular than that of the normoblast but still slightly coarser than that of the classic megaloblast. The open structure of the nuclear chromatin persisted in the later, acidophilic stages of cell development, and in the more mature forms differentiation from megaloblasts became indeed almost impossible. As in typical megaloblasts, abnormal mitoses, irregular chromatolysis, and pronounced karyorrhexis were common features of these intermediate cells, and many of the nuclei, especially those of the later stages, had bizarre shapes and showed extreme lobulation.

We concluded that this intermediate type of erythropoiesis represents an early stage of megaloblastic transformation of the bone marrow. We were led to this view by the following observations:

1. The cells designated as intermediate resembled megaloblasts in all but the finest cytologic details.

2. At least a few, and often numerous, classic megaloblasts were always found when erythropoiesis was of the intermediate type but were never seen by us in normoblastic marrows. Conversely intermediate cells were nearly always present when megaloblasts predominated in the marrow.

3. The actual progression of megaloblastic transformation was observed in one patient (Fig. 1) where specific treatment was deliberately withheld for one month after the initial marrow examination had shown an intermediate type of erythrocytogenesis. At the end of that time the anemia had recurred and a second marrow specimen showed a considerable increase in classic megaloblasts.

4. In every case where intermediate erythroblasts predominated in the marrow the abnormalities seen in the granulocytes were the same as in cases with a frankly megaloblastic picture. We have not seen this type of leucopoiesis in other conditions.

5. A specific effect of folic acid was demonstrable in every instance and, as will be shown the response followed the same pattern as that of the first group (Fig. 7).

These observations suggested that the megaloblastic transformation of the bone marrow is a gradual and progressive change in which the appearance of typical megaloblasts and promegaloblasts is a relatively late event. Our findings seem to indicate that the process may be recognized in its earlier stages by the application of more liberal criteria in regard to erythrocytogenesis. Even

the pattern of erythropoiesis which we have referred to as intermediate appears to be preceded by constant and specific changes in the granulocytes which may be utilized for early diagnosis. The marrow of the remaining two patients in our group (Cases 4 and 7) showed only minimal deviations from the normoblastic pattern, but the normal myelocytes were largely replaced by "giant metamyelocytes" and similar pathologic granulocytes. In both instances the administration of folic acid was followed by reticulocyte responses of specific character and by subsequent rises in hemoglobin and red cell counts without further treatment (Fig. 2). Similar effects of folic acid were not seen in anemias other than those associated with megaloblastic bone marrow.³

Fig. 3.—Case 8. Qualitative changes in erythropoiesis in response to folic acid.

Changes After Therapy.—In studying the marrow response to folic acid an attempt was made to obtain an over-all picture by taking samples at different intervals after the start of therapy. Therefore, the specimens taken from different patients were not always comparable as to the time when they were taken, but ranged from twelve hours to twenty-nine days, with most of the samples obtained in the first five days after treatment. Since it soon became evident that most of the significant changes took place during that period only a few observations were made in later stages.

Our only twelve-hour specimen came from a patient with a characteristic megaloblastic marrow pattern (Fig. 3). Before treatment almost no normo-

blastic cells were present. After twelve hours a significant change had occurred. Megaloblasts were still present but the vast majority of the cells had undergone a distinct change in appearance. Again, since they could not otherwise be classified, these cells were designated as intermediate in type. A small number of basophilic normoblasts was noted at this time.

At twenty-four hours the marrow of the same patient showed few megaloblasts and virtually all of these were acidophilic cells. There was a marked increase in basophilic and polychromatic erythroblasts which still did not appear entirely normal but closely resembled normoblasts. Simultaneously an appreciable number of basophilic normoblasts appeared. Numerous mitotic figures were seen.

At forty-eight hours erythropoiesis was typically normoblastic. There was a further marked increase in polychromatic erythroblasts.

At ninety-six hours a shift toward more mature cells had become evident. Almost 30 per cent of the erythroblasts were cells with oxyphilic cytoplasm.

Serial studies made on nine other patients showed a similar pattern (Figs. 4 to 7).^{*} On the basis of these composite observations the progression of marrow changes in response to folic acid may be summarized as follows: The megaloblasts lose their characteristic structure, and in twelve to twenty-four hours the erythroblasts assume an appearance intermediate between that of megaloblasts and normoblasts. Typical normoblasts can already be seen in small numbers. Almost the only megaloblasts still recognizable at this time are late, oxyphilic cells, and these disappear at the end of thirty-six hours. Two days after treatment has begun the transformation is virtually complete and the marrow is normoblastic.

The change in the cellular characteristics is accompanied by an increase of basophilic and, slightly later, of polychromatic cells and by the appearance of numerous mitotic figures. In the following days there is a relative decrease in basophilic erythroblasts, a further increase in polychromatic cells, and a steady increase in oxyphilic cells so that the distribution of erythroid cells gradually approaches the normal.

The shifts in the maturation curves of the erythroblasts were rather closely paralleled by shifts in the distribution of the mitoses (Fig. 8). Before treatment there was usually a relative increase in mitosis of basophilic cells and a corresponding decrease of mitosis in more mature erythroblasts. Following therapy an impressive increase in the proportion of polychromatophilic cells in mitosis took place (Fig. 9). This suggested that the earlier disturbance had affected mitotic activity chiefly at the level of the polychromatophilic erythroblasts and that one effect of specific therapy was the resumption of mitotic division at the normal level of cellular maturation.

Our findings indicate that only the late, oxyphilic megaloblasts escape the effect of folic acid and are not transformed into normoblasts, presumably because they are past the stage in cellular development where multiplication occurs. These cells continue their maturation and probably leave the marrow

^{*}To save space additional graphs showing the pattern in the four remaining cases have been omitted since they have essentially the same features as those shown.

as megalocytes. The younger megaloblasts, on the other hand, seem to be transformed almost quantitatively into normoblasts, even those already in the polychromatic stage. This is indicated not only by the enormous increase in polychromatic normoblasts early in the course of the response, an event which could hardly be explained by proliferation of the few residual normoblasts present before treatment, but more significantly by the virtually complete disappearance of megaloblasts in twenty-four to thirty-six hours. If the younger megaloblasts were not affected by the therapy but continued to mature as megaloblasts they should be demonstrable in proportionate numbers as oxyphilic megaloblasts in subsequent marrow samples. It appears likely, therefore, that as late as the polychromatic stage megaloblasts can utilize the hemopoietic principle and resume normal mitosis and normal morphologic characteristics.

Our observations on the evolution and regression of the megaloblastic pattern support neither the view that megaloblasts are normal constituents of the marrow nor the concept that these cells are genetically different from normal erythroblasts and immutably fixed in their characteristics by the nature of their ancestral cells. Instead we interpret our findings as evidence that in the absence of hemopoietic principle erythroblasts undergo a progressive aberration in structure as well as function which is reversible except in cells permanently incapable of mitosis. This concept in no way detracts from the diagnostic significance of the megaloblast.

QUANTITATIVE CHANGES

We are well aware of the limitations of measurements in the cellularity of the bone marrow.⁶ Nevertheless it seemed worth while to investigate the volumetric pattern of the aspirated marrow in our patients to see if a constant pattern was demonstrable. In regard to the total cellularity before therapy this was not the case. Table I shows that the height of the myeloid-erythroid layer in the initial samples was too variable to be significant in itself. However,

TABLE II. CHANGES IN THE MYELOID-ERYTHROID LAYER WITH FOLIC ACID THERAPY

[illegible]

Fig. 11.—Increase in erythroid layer of buffy coat after folic acid therapy in twelve of fifteen cases. Dotted lines indicate only one marrow sample taken after treatment.

a substantial rise in the myeloid-erythroid volume was observed after therapy in eleven of the fifteen patients, suggesting a significant trend (Table II).

When the height of the myeloid-erythroid layer after centrifugation was recorded in volumes per cent and the proportion of erythroblasts determined by differential counts of 500 nucleated cells, the volume of erythroblasts could be expressed in per cent of the total sample, giving a sample measure of erythropoietic activity. Using these values we found rather good correlation between the initial erythroid cell volume in the marrow and the severity of the anemia (Fig. 10). Surprisingly enough, erythroid hyperplasia was the more marked the higher the hemoglobin; it was slight or absent in patients

Fig. 12.—Case 6. The effect of folic acid on the height and constituents of the myeloid-erythroid layers.

with severe anemia. This behavior of the erythroid marrow cells is in contrast to that of uncomplicated pernicious anemia in the adult⁷ and suggests a non-specific depression of erythropoiesis probably related to the presence of active infection superimposed on the deficiency of hemopoietic principle.

When the erythroid cell volume alone was used as a measure of the response to therapy, a clear-cut increase was demonstrable in twelve of the fifteen cases (Fig. 11), a decrease in two (Cases 4 and 10), and no appreciable

change in one (Case 13). This trend indicates that, for the purpose of a comparative study at least, the method used by us is valid. Using this measure it became evident that in two of the four subjects in whom a drop in the total myeloid-erythroid layer occurred after therapy the decline was not due to a decrease in erythroblasts but to a decrease of other marrow cells (granulocytes and lymphocytes). In one of these subjects (Case 7) the erythroid cells actually increased significantly in spite of the total decrease in myeloid-erythroid volume.

In some instances the rise in the volume of erythroid cells was tremendous, amounting to a thirty fold increase in twenty-four hours in one patient (Fig. 12). Of the two instances in which a drop occurred, one was in a patient (Case 10) whose blood showed reticulocytosis of 8.2 per cent before treatment and who may have been at the beginning of a spontaneous remission. In both patients the initial marrow had shown considerable erythroid hyperplasia before treatment.

There was no apparent proportionality in our material between the extent of the increase and the maximal erythroid hyperplasia achieved on the one hand and the reticulocyte response and hemoglobin response on the other. This lack of correlation may be ascribed to a number of factors operating in our patients; namely, the effects of transfusions, the presence of infection and the effectiveness of the treatment directed against infection, the age differences, the factor of prematurity in one instance (Case 7), and the possible effects of coexisting deficiencies.

SUMMARY AND CONCLUSIONS

Serial studies of the bone marrow in fifteen patients with infantile megaloblastic anemia responding specifically to folic acid therapy as shown by reticulocytosis and rise in hemoglobin and red cell counts demonstrated a spectrum of gradual and progressive aberrations in the appearance of the erythroblasts. The patterns ranged from predominantly normoblastic to frankly megaloblastic cells with many intermediate types which could not be classified in either category. The classic megaloblastic dysplasia is interpreted as only an extreme deviation from normal structure; earlier, less striking changes are significant as shown by the therapeutic test. By the use of more liberal criteria regarding the classification of erythroblasts and by the recognition of constant and specific changes in the granulocytes of the marrow, the disturbance resulting from a marrow deficiency in hemopoietic principle can be detected before the classic megaloblast stage has developed. The lack of hematopoietic principle leads to a disturbance in mitosis, and specific therapy results in a prompt return to normal mitotic activity.

Within twenty-four hours after the intramuscular injection of folic acid clear-cut morphologic changes take place in the marrow of these patients and a response in the peripheral blood can be predicted. Folic acid produces a prompt return to the normoblastic type of erythropoiesis. The immediate transformation of all but the most nearly mature megaloblasts suggests that the megaloblastic dysplasia of the individual cells is reversible so long as the

cell remains capable of mitosis. In the course of the transformation the pathologic cells pass again through an intermediate stage.

In megaloblastic anemia of infancy the total myeloid-erythroid volume of aspirated marrow samples shows no correlation with the degree of anemia and is not a reliable index of the response to therapy, but the calculated volume of erythroid cells shows a direct proportionality to the severity of the anemia and a significant rise in response to therapy.

FOLIC ACID THERAPY IN NONTROPICAL SPRUE: RESULTS OF TREATMENT IN SEVEN CASES

JAMES F. WEIR, M.D., AND MANDRED W. COMFORT, M.D.
ROCHESTER, MINN.

DURING the latter part of 1945 Spies and associates¹ reported that synthetic folic acid exerted a favorable influence on the course of macrocytic anemias. Included in their study were patients with tropical sprue in whom the favorable response was not only hematologic but also general. The symptoms referable to the alimentary tract in these patients also tended to subside when folic acid was employed. Subsequent reports include those of Darby and of Spies and their associates²⁻⁴ and occasional instances of sprue in papers of other workers who were chiefly concerned with pernicious anemia.

Davidson, Girdwood, and Innes⁵ recently reported results of short periods of treatment with folic acid in ten patients with tropical sprue, idiopathic steatorrhea, and celiac disease. They were primarily interested in the hematologic response which they found disappointing. The clinical response was excellent in the patients with tropical sprue and idiopathic steatorrhea, but improvement was lacking in the patients with celiac disease. Studies of fat balance were made before and after treatment in seven patients (including one with celiac disease). In only one patient was there improvement in absorption of fat.

Nontropical sprue is a condition characterized by diarrhea, steatorrhea, and other gastrointestinal symptoms, macrocytic anemia, glossitis, nutritional manifestations including loss of weight, weakness, hypocalcemia, osteoporosis, tetany, hypoproteinemia, edema, and other changes. These manifestations may vary considerably from patient to patient. The disease, furthermore, is characterized by a chronic progressive course and often prolonged remissions. Treatment in the past has been based chiefly on the use of a low fat diet and administration of liver extract, calcium, and the various vitamins. In general, the results of treatment have been disappointing. In most cases remission occurred, but the tendency to spontaneous remission has rendered the interpretation of the value of therapeutic agents most difficult.

Stimulated by earlier reports of Spies and co-workers⁶ our group has treated seven patients who had nontropical sprue with synthetic folic acid.* These form the basis for this report. The criteria of nontropical sprue were fulfilled in the opinion of the several consultants who saw the patients. None of the patients had lived in a tropical country.

PLAN OF STUDY

Control data were obtained before institution of treatment. The history included notes about the frequency, duration, and severity of the exacerbations

From the Division of Medicine, Mayo Clinic.

Received for publication, Aug. 1, 1947.

*The folic acid was kindly supplied by the Lederle Laboratories, Inc., Pearl River, N. Y.

and about the severity of the disease between exacerbations, including frequency and character of stools. Hematologic studies included sternal aspiration and examination, determination of the concentration of hemoglobin in grams, erythrocyte, leucocyte, and reticulocyte counts, and measurement of the erythrocytes with an erythrocytometer. The concentrations of calcium, phosphorus, total protein, albumin, and globulin in the serum, as well as values for phosphatase and prothrombin times, were determined. Roentgenograms of the skull, hands, and teeth for osteoporosis and of the small bowel to exclude ileitis and to check for the so-called deficiency pattern were secured. Roentgenologic examination of the small bowel was not repeated because changes during periods of improvement had not been observed in past experience. In four subjects the fecal solids, fat, and nitrogen were determined each day during the three-day test period while the patient was receiving a standard test diet of 101.6 Gm. of fat, 117.5 Gm. of protein, 269.6 Gm. of carbohydrate, and 2,463 calories. On completion of the preliminary survey a diet was used containing 50 to 100 Gm. of fat and 120 Gm. or more of protein and carbohydrates to raise the calorie intake to 3,000 to 3,500. Vitamins, including sufficient vitamin K to control hypoprothrombinemia, were given. The dosage of folic acid usually was 50 mg. daily by the intramuscular route. One patient received 180 mg. daily intramuscularly for two weeks while another received only 15 mg. orally from the start. Hematologic and chemical determinations on the blood were made each week; the reticulocyte count was taken every other day.

Five of the seven patients were kept under observation at the clinic for four weeks or longer. On dismissal from the clinic the patients continued to take folic acid intramuscularly or orally, the usual vitamins, and, in most cases, calcium lactate in doses of 1 dram (3.9 Gm.) three times daily. Some also subsequently were given liver extract. All were urged to use a high carbohydrate, high protein, low fat diet. The dosage of folic acid is indicated in the individual case reports and in Table I.

Some of the patients subsequently returned for observation and hematologic and chemical studies on the blood. In two subjects the losses of fecal solids, fat, and nitrogen were determined after eight and twelve months of treatment with folic acid. In two others the fecal components could not be determined because of refusal of the patient or because of his condition.

Each subject on his return home was requested to keep a diary in which was recorded the number of stools passed daily as well as other manifestations of the disease.

CASE 1.—A 51-year-old man complained of diarrhea of forty months' duration. The stools were steatorrheal in type and averaged about three daily except during exacerbations, when they numbered as many as ten and fifteen daily. He had lost much strength and 25 pounds (11.3 kilograms). No tetany had been experienced.

Examination revealed undernutrition, for the patient weighed only 110 pounds (50 kilograms), and pigmentation of the skin. Free hydrochloric acid (20 units, by Töpfer's method) was found on gastric analysis. Roentgenologic studies revealed a so-called deficiency pattern in the small intestine. When the standard test diet of 101.6 Gm. of fat and 117.5 Gm. of protein was used, the average daily loss of fat and nitrogen was, respectively, 41 and 5.8 Grams. Stools averaged seven per day during the test period (Table II). An oral glucose

*A standard test diet containing 101.6 Gm. of fat, 117.5 Gm. of protein, 269.6 Gm. of carbohydrate, and 2,163 calories. Marker technique employed.

†Study conducted during exacerbation of disease.

tolerance test presented a flat curve. The value for serum protein was 6.1 Gm. per 100 c.c. and the albumin globulin ratio was 1.4:1. Serum calcium measured 8.8 mg. per 100 c.c.; there were 12.3 Gm. of hemoglobin per 100 c.c. of blood, and erythrocytes numbered 4,300,000 per cubic millimeter of blood, of which 1 per cent was reticulocytes. General macrocytosis was present. The sternal bone marrow was normoblastic. Folic acid was given intramuscularly in 50 mg. doses each day. During thirty days of observation the patient did not gain weight, strength, or sense of well being in spite of a daily intake of 3,000 to 3,500 calories. Frequency of stools did not change; the number varied from one to five daily. At the end of this period the value for hemoglobin was 11.6 Gm. per 100 c.c., and erythrocytes numbered 3,470,000 per cubic millimeter. The highest reticulocyte count was 3.3 per cent encountered on the sixth day of therapy. Throughout this period the erythrocytes measured 8.1 to 8.3 μ in diameter. Serum proteins then measured 6.8 Gm. per 100 c.c., the albumin globulin ratio was 1.09:1, and the value for serum calcium was 9.3 mg. per 100 cubic centimeters.

After dismissal the patient continued the nutritious diet and daily intramuscular injections of 50 mg. of folic acid. In spite of this treatment he returned in one month because of an acute exacerbation of the disease characterized by abdominal pain, distention, diarrhea, vomiting, abdominal tenderness, and loss of 10 pounds (4.5 kilograms). On examination he was acutely ill and gave evidence of dehydration, acidosis, and azotemia. With correction of these conditions the acute symptoms subsided. He remained under observation another month, during which time administration of the folic acid was continued. He gained a few pounds but mild diarrhea persisted. At the end of this period the concentration of hemoglobin was 11.2 Gm., erythrocytes numbered 4,000,000, macrocytosis persisted with erythrocytometer readings of 8 and 8.4 μ , and the value for serum proteins was 6.1 Gm. per 100 cubic centimeters. On dismissal he was instructed to take 50 mg. of folic acid daily by mouth. This treatment was continued for six more months, during which time the patient did not improve; mild diarrhea with exacerbations periodically continued, and gain in weight did not occur.

The patient then returned for further observation. At this time the value for hemoglobin was 9.6 Gm. and erythrocytes numbered 3,580,000. The general macrocytosis persisted. The erythrocytometer reading was 8.0 μ , the concentration of serum protein was 5.5 Gm. per 100 c.c., the albumin-globulin ratio was 1.1:1, and the value for serum calcium was 8.2 mg. per 100 cubic centimeters. Average daily loss of fecal solids, fat, and nitrogen again was determined (Table II); stools numbered two daily during the test period. Comparison of these data with similar data obtained before treatment disclosed that loss of fat was essentially the same but that nitrogen loss was less during the period after treatment. However, the improvement, in our opinion, is due not to the folic acid but to the state of the disease at the time the data were obtained. More fat was lost during the first period of study and during an exacerbation of the disease than during the second period of study which was made at a time when an exacerbation was not present. The differences are small and probably not significant.

Comment.—The course of the disease has not been changed by treatment with synthetic folic acid, diet, and vitamins. In fact the course has been chronic and gradually downhill in spite of treatment for nine months. Severe exacerbations have occurred; weight has not been gained. The degree of anemia and of hypocalcemia has fluctuated slightly but has remained essentially the same at the last examination as at the first one. Hypoproteinemia has appeared.

CASE 2—The patient, a woman first seen when she was 29 years of age, had had a lifelong tendency to loose stools but this had been worse during the four years preceding admission. Weight had declined from 130 to 103 pounds (59.0 to 46.7 kilograms), slight edema had occurred, and tetany had been noted for one year. Stools were 64 to 74 per cent fat (dry weight). Gastric analysis revealed 20 units of free acid. Roentgenologic examination of the small bowel revealed a deficiency pattern. The concentration of hemoglobin was 15 Gm per 100 c.c. of blood; erythrocytes numbered 4,190,000; the value for serum protein

was 5.6 Gm., and for serum calcium, 6.6 mg. per 100 cubic centimeters. Until the next period of observation (period of the present study) when the patient was 33 years old, mild diarrhea had continued; an average of three to four loose stools were passed daily. Slight edema and latent tetany also continued. Weight was 101 pounds (45.8 kilograms). Laboratory studies revealed general osteomalacia of the bones, a flat oral glucose tolerance curve, 7.1 mg. of calcium and 5.9 Gm. of proteins per 100 c.c. of serum, albumin-globulin ratio of 2.2:1, 7.6 Gm. hemoglobin, 3,610,000 erythrocytes, hypochromic normocytic erythrocytes, an erythrocytometer reading of 7.4 μ , and hyperplastic normoblastic sternal marrow. For four weeks a diet of 3,000 to 3,500 calories (fat, 75 Gm.; protein, 150 Gm.) was taken well without significant diarrhea. During this time 50 mg. of folic acid were given intramuscularly daily. A gain of five pounds (2.3 kilograms) occurred. This gain in weight was credited to increased intake of food and to rest. At the end of this period the value for hemoglobin was 8.25 Gm., erythrocytes numbered 3,610,000, the erythrocytometer reading was 7.6 μ , the value for serum protein was 6.6 Gm., the albumin-globulin ratio was 2.18:1 and serum calcium, 7.9 mg. per 100 cubic centimeters. After the institution of folic acid therapy the highest reticuloocyte count was 3 per cent on the fifth day of treatment. In general, the patient noted no subjective improvement. She returned home with instructions to continue the highly nutritious diet (3,500 calories with 75 Gm. of fat and 150 Gm. of protein) and to take a multivitamin tablet, iron, and 15 mg. of folic acid daily. At first the folic acid was taken intramuscularly and later, orally.

When the patient returned eight months later, she stated that her weight had increased to 113 pounds (51.3 kilograms) and then had dropped to 96 (43.5 kilograms) because of inability to eat during an exacerbation three months previously. Diarrhea had been troublesome only during the exacerbation, but tetany occurred at intervals and variable edema had been present. Folic acid therapy had been interrupted only for a time during relapse. The weight was 96 pounds. Laboratory studies revealed 6.4 Gm. of hemoglobin per 100 c.c. of blood, 4,010,000 erythrocytes, hypochromic normocytic erythrocytes, an erythrocytometer reading of 7.4 μ , 5.3 Gm. of calcium and 5.3 Gm. of protein per 100 c.c. of serum, and an albumin-globulin ratio of 2.32:1. The patient was placed on the standard test diet both before and after treatment with folic acid, and the values for fecal fat and nitrogen were determined. The severity of the disease apparently was the same during each period of study, the stools numbering one or two daily. After treatment the average daily loss of fats was greater than before treatment but the loss of nitrogen was not significantly different. Therapy with folic acid did not decrease the loss of fat and nitrogen in the feces.

Comment.—Slight gain in weight and improvement in the degree of hypoproteinemia and hypocalcemia occurred, as is so often the case in nontropical sprue, with or without treatment. The temptation to ascribe the improvement to folic acid is disputed by the occurrence of a severe exacerbation while receiving 15 mg. of the drug intramuscularly or orally each day. The course of the disease has not been altered.

CASE 3.—A 37-year-old woman had had symptoms of nontropical sprue for three years. Diabetes mellitus had been discovered about the same time. One and one-half years before admission an exacerbation of the sprue syndrome had occurred, during which glossitis was marked and weight had declined from 105 to 78 pounds (47.6 to 35.4 kilograms). Three months later tetany was noted. At the time of admission the patient was not suffering from diarrhea but the stools appeared fatty. Weight was 81 pounds (36.7 kilograms). Laboratory findings were as follows: glycosuria, 1.39 per cent; blood sugar, 185 to 226 mg. per 100 c.c.; osteoporosis of the skull, spinal column, and bones of the hands; and 14 units of free gastric acid. There was roentgenologic evidence of a deficiency pattern in the small intestine. On the standard test diet the average daily losses of fecal solids, fat, and nitrogen were, respectively, 67, 25, and 3 grams. The value for serum calcium was 7.9 mg. and for serum protein, 6.2 Gm. per 100 c.c.; the albumin-globulin ratio was 1.46:1; the concentration of hemoglobin was 12.7 Gm. per 100 c.c.; erythrocytes numbered 4,300,000, of which 1.1 to 2.2

per cent were reticulocytes; general macrocytosis was indicated by erythrocytometer readings of 7.8 to 8.0 microns. A diet containing 2,700 to 3,000 calories, with fat limited to 100 Gm. or less daily, was taken well. The requirements for insulin were met. A gain in weight from 81 to 103 pounds (36.7 to 46.7 kilograms) occurred in seven weeks; about 10 pounds (4.5 kilograms) were gained during the week of observation before folic acid was started. Usually the patient had two or three stools daily but at times constipation was present. After one week's observation folic acid was administered intramuscularly in doses of 15 mg. daily for two weeks, then 30 mg. twice daily for one week, 90 mg. twice daily for two weeks, and finally 90 mg. daily for one week. During this time the gain in weight just mentioned continued. At completion of observation the value for hemoglobin was 13.8 Gm. and erythrocytes numbered 4,120,000; macrocytosis had persisted for the erythrocytometer reading varied from 7.9 to 8.1 microns. The highest reticulocyte count was 2.4 per cent on the seventh day of treatment. Sternal marrow was normoblastic at the time of completion of observation. The value for serum protein was 7.1 Gm., the albumin-globulin ratio was 1.6:1, and the value for serum calcium was 7.9 mg. per 100 cubic centimeters. After return home the patient continued to take folic acid intramuscularly in 15 mg. doses daily and progressed well for three months, when an acute exacerbation of the sprue syndrome developed which led to death.

Comment.—Synthetic folic acid did not alter the course of the disease in this case.

CASE 4.—The patient, a woman, was first seen when she was 24 years of age. Symptoms of nontropical sprue had been present for seven months. Diarrhea, loss of 20 pounds (9.1 kilograms), glossitis, transitory edema, and tetany had occurred. The concentration of hemoglobin was 43 per cent (Dare); erythrocytes numbered 4,060,000. The value for serum protein was 5.45 Gm. and for calcium, 8.7 mg. per 100 cubic centimeters. The value for free gastric acidity was 30 units (Töpfer's method). Stools contained an excess of fat.

When the patient returned seven years later at the age of 31, weakness and tetany were the chief complaints. Diarrhea was present. The blood presented a picture of marked hypochromic macrocytic anemia, the concentration of hemoglobin was 7.0 Gm. per 100 c.c. of blood, and erythrocytes numbered 3,180,000 per cubic millimeter. Mild symptoms continued and at the time of the next visit at the age of 41 the patient complained that diarrhea was troublesome. Weight was then 103 pounds (46.7 kilograms). Free gastric acids measured 36 units. Roentgenologic examination of the small intestine revealed a deficiency pattern. On the standard test diet, the average daily loss of fecal solids, fat, and nitrogen were, respectively, 38, 14, and 2 grams. An oral glucose tolerance test gave a flat curve. The value for serum calcium was 8.0 mg. and for serum protein, 6.2 Gm. per 100 c.c.; the albumin-globulin ratio was 2.06:1. The concentration of hemoglobin was 10.8 Gm. per 100 c.c. and erythrocytes numbered 3,090,000, of which 0.4 to 1.6 per cent were reticulocytes. Macrocytosis was marked. Sternal aspiration revealed megaloblastic marrow. After intramuscular administration of 50 mg. of folic acid daily slight reticulocytosis occurred, the highest reading being 4.9 per cent on the fifth day of treatment. Two weeks later the sternal marrow was normoblastic. After six weeks the value for hemoglobin was 12.0 Gm. per 100 c.c. and erythrocytes numbered 3,860,000. Erythrocytometer readings during the period of treatment varied from 8.5 to 7.8 microns. At the end of the period of observation (six weeks) the value for serum calcium was 9.1 mg. and for serum protein, 7.7 Gm. per 100 c.c.; the albumin-globulin ratio was 1.34:1. During this period of treatment the patient took a 3,500 calorie diet daily (100 Gm. of fat and 120 Gm. of protein). Several mild exacerbations of the diarrhea occurred (seven to ten stools daily); weight increased to 106 pounds (48.1 kilograms), a gain of only 3 pounds (1.4 kilograms).

Following dismissal the patient continued to use a high caloric diet (fat, 50 Gm. and protein, 160 Gm.) and to take 15 mg. of folic acid orally each day. The exacerbations of diarrhea, as well as varying degrees of edema and tetany, have continued to occur, and, on one occasion, a peculiar generalized paralysis occurred. On several occasions during this eight-

month interval hospitalization for treatment became necessary. Liver extract, calcium, vitamins, and intravenously administered amino acids have been used together with folic acid.

Comment.—The condition of this patient remains pitiful in spite of treatment not only with folic acid, but with other agents as well.

CASE 5.—The patient, a 42-year old woman, had been anemic at varying times for twenty years and had always had a tendency to loose stools. For ten years the stools had at times been more frequent than before and were described as foamy. The chief complaint was fatigue and weakness, and she had lost 5 pounds (3.6 kilograms) in three months. Weight was 128 pounds (58.1 kilograms). Laboratory studies revealed 11.9 Gm. of hemoglobin, 3,030,000 erythrocytes, general macrocytosis with an erythrocytometer reading of 8.3 μ , 9.1 mg. of serum calcium and 6.2 Gm. of serum protein per 100 cc., and an albumin globulin ratio of 19.1. There was a deficiency pattern in the small intestine on roentgenologic examination. Gastric analysis revealed 52 units of free acid; the oral glucose tolerance curve was flat and the stool contained 31 per cent fat (dry weight) while the patient was taking only 100 Gm. of fat each day. Sternal marrow was macronormoblastic in type. Folic acid in doses of 50 mg. was given orally each day. The highest reticulocyte count was 3 per cent on the eighth day of treatment. After three weeks of treatment the value for hemoglobin was 10.2 Gm. and erythrocytes numbered 3,810,000. After two months of treatment macrocytosis was still present, and the erythrocytometer reading was 8.2 microns. The patient's strength was good but no weight had been gained and episodes of diarrhea continued. Five months after institution of treatment, during an episode of diarrhea, a hemorrhagic state of extensive degree developed and was promptly controlled by administration of vitamin K. During this episode the patient was hospitalized elsewhere and a loss of 10 pounds (4.5 kilograms) in weight occurred. On her return to the clinic the value for hemoglobin was 10.8 Gm., and erythrocytes numbered 4,080,000. Her condition remained fairly stationary for the next month and then the diarrhea became much worse, six to eight stools occurring daily. Weight dropped to 105 pounds (47.6 kilograms). She was again hospitalized and additional measures, including liver extract, were instituted to control symptoms. Folic acid was given intramuscularly instead of orally. Improvement gradually developed. The value for hemoglobin was 9.4 Gm., erythrocytes numbered 3,300,000, the erythrocytometer reading was 8.2 μ , and 19 per cent of the erythrocytes were reticulocytes. Stools contained 32.7 per cent fat by dry weight.

Comment.—In addition to absence of response hematologically or clinically to folic acid this patient presented an episode of hypoprothrombinemia with hemorrhage and an acute exacerbation of the intestinal symptoms while faithfully adhering to a regimen which included folic acid.

CASE 6.—A 53 year old woman had been seen on numerous occasions during the preceding ten years. At the first observation in 1936 cholecystectomy was performed for chronic cholecystitis with cholelithiasis. Exploration of the abdomen was otherwise normal. Moderate gastric retention was present preoperatively and at intervals postoperatively. During convalescence diabetes mellitus became manifest but was readily controlled. Weakness was also a prominent complaint. When the patient was 51 years of age, abdominal cramps, distention, and spells of diarrhea developed. Stools were bulky and light in color. Weight had declined from 99 to 88 pounds (44.9 to 39.9 kilograms). Blood counts which had previously been normal now revealed anemia. There were 11.6 Gm. of hemoglobin per 100 cc. of blood, 3,340,000 erythrocytes, 6.3 mg. of serum calcium and 6.8 Gm. of serum protein per 100 cc., and the albumin globulin ratio was 18.1. Stools contained 48.6 per cent fat. The patient received the usual treatment for sprue consisting of a low fat diet, liver extract, calcium lactate, and vitamin supplements. When seen a year later (the time of the present study) symptoms had persisted and weight had declined to 81 pounds (36.7 kilograms). No edema or tetany had been noted and the diabetes had not been a problem. Laboratory study now disclosed 10.5 Gm. of hemoglobin per 100 cc., 4,250,000 erythrocytes, and general macrocytosis with an erythrocytometer reading of 8.6 microns. The value for serum protein was

6.1 Gm. per 100 c.c.; the albumin globulin ratio was 1.7:1; the value for serum calcium was 8.2 mg. per 100 cubic centimeters. The fecal solids were 65.3 per cent fat. Sternal marrow appeared normoblastic. In addition to previous therapy, 50 mg. of folic acid were given daily by mouth. Two months later the symptoms and the general status of health and bowel function had not changed. The value for hemoglobin was 10.5 Gm. per 100 c.c., and erythrocytes numbered 1,290,000. The general macrocytosis had persisted; the erythrocytometer reading was 8.3 microns.

Comment.—Folic acid had evidently accomplished little in this period.

CASE 7.—A 17-year old girl had had episodes of diarrhea since infancy. These occurred about once a month and lasted three to five days; the stools, which numbered ten to twenty daily, were greasy and foamy. Growth was much retarded. She was $4\frac{1}{2}$ feet, 10 inches (147.3 cm.) tall and weighed 79 pounds (35.8 kilograms); menses had not been established. Edema had been noted on several occasions. The occurrence of tetany was questionable. The value for hemoglobin was 11 Gm. per 100 c.c., erythrocytes numbered 5,260,000, and macrocytosis was present. The stools were 52.7 per cent fat (dry weight). The value for serum protein was 4.8 Gm. per 100 c.c.; the albumin globulin ratio was 1.4:1. The concentration of serum calcium was 8.5 mg. per 100 c.c. and the sternal marrow was normoblastic. A regimen consisting of 3,000 calories per day (50 Gm. of fat), liver extract (1 c.c. weekly), and folic acid (15 mg. daily by mouth) was instituted.

The patient returned twelve months later. Monthly exacerbations of diarrhea had continued until two months prior to this visit. Some of the exacerbations were the most severe she had had. She had gained 14 pounds (6.4 kilograms) and had grown $3\frac{1}{2}$ inches (9 cm.). The menstrual periods had not become established although pelvic pain for one to three days each month had occurred. Pigmentation had lessened. The breasts were still undeveloped; some pubic hair was present. The concentration of hemoglobin was 9.8 Gm per 100 c.c. of blood; erythrocytes numbered 4,600,000 per cubic millimeter, of which 1.8 per cent were reticulocytes. Some hypochromasia and a borderline type of macrocytosis were noted in the blood smear. The value for protein in the serum was 5.9 Gm. per 100 c.c.; the albumin globulin ratio was 1.99:1. The concentration of serum calcium was 9.5 mg. per 100 cubic centimeters. The stage of bone development corresponded to that of a child 13 years old.

Comment.—Definite improvement occurred in this case and was attributed to improvement in nutrition. It is impossible to determine whether this was due to the improved intake of food or to a natural remission in the disease or to the results of medication. A further period of treatment will be required to determine the principal factor in the improvement, and such a conclusion may not be possible even then.

COMMENT

Most important in the discussion of these cases is a consideration of the general status of the patients' health. Only two patients have shown any significant gain in weight or improvement in strength or sense of well-being (Cases 3 and 7). One patient (Case 3) had had symptoms of nontropical sprue and diabetes mellitus for three years. No diarrhea was present on admission although the stools contained excess fat. Before treatment with folic acid was started she had gained 10 pounds and further gain was accomplished after this treatment was instituted. This gain was considered to be due largely to an increased intake of food and control of the diabetes as the sprue was in remission at the time of admission. At the time of dismissal the patient was taking 15 mg. of folic acid daily by mouth and she progressed well for three months.

Then an exacerbation of the sprue syndrome resulted in death. The other patient (Case 7) showed definite improvement but it is not possible to state the chief factor responsible for this. The patient in Case 1, who gave a three-year history of sprue, continued to take 50 mg. of folic acid daily intramuscularly at home for one month. At the end of this time an exacerbation of the disease caused him to return to our care. He was in a critical condition as evidenced by dehydration, acidosis, and azotemia. In spite of continuation of treatment with folic acid as well as other therapeutic management for six months, his general condition did not improve nor intestinal manifestations decrease. One patient (Case 4) who had had indications of sprue for seventeen years continued to have exacerbations with varying degrees of edema and tetany, and on one occasion a peculiar paralysis, while taking 15 mg. of folic acid daily by mouth. This patient has required frequent hospital admissions during the subsequent eight months. The patient in Case 5, while taking 50 mg. of folic acid daily for six months, has had an episode of hypoprothrombinemia (not uncommon in nontropical sprue) with hemorrhagic manifestations and a subsequent acute exacerbation of the intestinal symptoms of the disease. Two patients (Cases 2 and 6) did not improve during nine and two months, respectively.

In general, the diarrhea and steatorrhea present before treatment with folic acid have continued during treatment, often with severe flare-ups, and there has been no gain in weight, strength, or sense of well-being that could not be attributed to remissions in the disease and improved intake of food. The levels of calcium or protein in the blood and manifestations of tetany or edema, when present, have not been improved permanently in any case, even with improved intake of food or other procedures.

Some anemia was present in all cases at the time of admission, but the value for hemoglobin was 10 Gm. or more in all but one. The lowest erythrocyte count was 3,030,000. No significant changes in blood counts were obtained from treatment with folic acid. Details are given in Table I. General macrocytosis was present in all patients except one, and this patient (Case 2) had the most marked anemia. The macrocytosis persisted after treatment with folic acid in each of the five cases in which re-examination has been done. No change in the erythrocytometer reading was encountered except in Case 4. In this instance the size of the erythrocytes decreased somewhat coincident with a change in the sternal marrow from megaloblastic to normoblastic type. The highest reticulocyte count after commencement of treatment with folic acid was 4.9 per cent on the fifth day of treatment. In general there was little change in the reticulocyte count. However, the degree of anemia on admission was not such that a great response would be expected. In one case megaloblastic bone marrow present before treatment became normoblastic after treatment. In four other cases the sternal marrow was normoblastic before treatment was started. Some of these patients undoubtedly had taken liver extract at varying times before the observations at the clinic. In general, and in spite of this, the hematologic response in this group of cases has been disappointing; the anemia has not improved and the macrocytosis has persisted.

SUMMARY

The following statements seem justified from our observation of this group of seven cases of nontropical sprue. Treatment with folic acid has not resulted in improvement in the sense of well-being or in gain in weight or strength that could not be accounted for by increased intake of food and natural remission of the disease. The frequency or severity of the exacerbations of the intestinal manifestations of the disease has not changed. The hematologic response has been disappointing since anemia and macrocytosis have persisted. All this is in contrast to the favorable results reported in the literature regarding response of tropical sprue to treatment with folic acid. Whether the two conditions are different or whether the condition in our cases had advanced to an irreversible stage and become resistant to treatment with folic acid is impossible to state. These results indicate that, in some cases at least, nontropical sprue does not respond favorably to treatment with folic acid.

URINARY PHENOLS IN PERNICIOUS ANEMIA

MARIAN E. SWENDSEID, PH.D., BENJAMIN WANDRUFF, M.D., AND
FRANK H. BETHELL, M.D.

ANN ARBOR, MICH.

ALTHOUGH physiologic changes in pernicious anemia are widespread, affecting the hematopoietic, digestive, and nervous systems, the development and course of the disease have not been shown to be closely associated with any specific biochemical disturbance. Therefore, evidence suggesting that the metabolism of the aromatic amino acid, tyrosine, may be altered in pernicious anemia is of considerable interest.

Observations bearing on the metabolic behavior of tyrosine in pernicious anemia indicate that in this disease blood phenol levels are high,¹ the urinary levels of the volatile phenols are lower in relapse than in remission,² and the urinary excretion of total phenolic compounds is increased in untreated cases.³ Jacobson and Subbarow⁴ have reported that 1-tyrosine increases the therapeutic activity of their primary antipernicious anemia factor. Since tyrosine is the presumed precursor of melanin pigment, the pigmentation changes frequently observed in pernicious anemia, which include graying of the hair and vitiligo, might also be considered as supportive evidence of the altered metabolism of tyrosine in this disease.

The present study was made to investigate further the metabolism of tyrosine in pernicious anemia by a fractionation of urinary phenolic compounds before and during initial treatment of the disease.

CLINICAL MATERIAL AND METHODS

Seven patients with pernicious anemia were employed in this study. They had not received antianemia therapy for at least six months prior to the present study. All of them had macrocytic anemia with erythrocyte levels below 3,000,000 per cubic millimeter. Histamine refractory achlorhydria was demonstrated in each instance, and all of the patients responded in the expected manner to the administration of antipernicious anemia medication.

Urine specimens were collected for two twenty-four hour periods immediately preceding the institution of therapy and for several twenty-four hour periods at intervals thereafter.

The urinary phenolic compounds were fractionated according to an unpublished method of Shacter and Lewis.⁵ By this method, after preliminary hydrolysis, the urine was extracted with ether and the ether-soluble portion extracted first with sodium bicarbonate and then with sodium hydroxide. Phenols were determined by the Medes^{6b} modification of the method of Folin and Ciocalteu^{6a} on each of the three fractions resulting from this procedure: (1) the ether-insoluble fraction, (2) the ether-soluble-bicarbonate-soluble fraction, and (3) the ether-soluble-bicarbonate-insoluble-hydroxide-soluble fraction. This last fraction will be referred to as the ether-soluble-hydroxide-soluble fraction.

The ether-insoluble fraction contains any tyrosine excreted as such in the urine. The ether-soluble urinary phenolic compounds which are extracted with the weak alkali, sodium

Received for publication, Aug. 1, 1947.

bicarbonate, are assumed to be, for the most part, aromatic hydroxy acids. Phenol and cresol are the only known phenols present in the urine in considerable amounts which are so weakly acidic that they cannot be extracted from another solution except with a strong alkali such as sodium hydroxide.

RESULTS

In Table I the results of the fractionation of urinary phenolic compounds before and after the institution of specific therapy are presented for seven patients with pernicious anemia.

*Treatment instituted on this day. In all patients except B. I. this treatment was 1 c.c. of 15 unit liver extract by intramuscular injection three times weekly. In the case of B. I. the treatment was 40 Gm. of ventriculin daily.

Values expressed as milligrams of tyrosine excreted per twenty-four hours.

In every patient except one (W. A.) the excretion of total phenols was greater in the relapse than in the remission state. This lowering of phenolic excretion levels occurred whether remission was induced by a liver extract or by desiccated stomach (ventriculin). The rapidity with which the excretion of the phenols is decreased should be noted. The decrease occurs within forty-eight hours after the institution of therapy and precedes any change in the corpuscular elements of the blood, including reticulocytosis. These results are

in agreement with our preliminary observations on the excretion of keto acids and hydroxyphenyl compounds by four patients with pernicious anemia which are not included in the present study.³

The increased excretion of total phenols in the relapse period is wholly attributable to an increase in the excretion of ether-soluble-bicarbonate-soluble phenols, the fraction containing the hydroxyphenyl acids. The identity of this acid, or acids, has not been established. Although in a previous report,³ using the method of Penrose and Quastel,⁴ we obtained a greater keto acid excretion during the relapse period of pernicious anemia, in this series of patients we were unable to confirm this observation consistently and, in several cases, tests for keto acids in the ether-soluble urine fraction gave negative results.

The ether-soluble-hydroxide-insoluble fraction either remained the same or increased somewhat after therapy. When an increase occurred, it was more apparent in the urine samples collected several days after therapy was first administered. In this connection, Volterra² also observed in pernicious anemia an increase in volatile phenols when remission was induced.

An effect of antipernicious anemia therapy to which there is no exception in the cases presented here is the reduction in the ratio of the ether-soluble-bicarbonate-soluble fraction to the ether-soluble-hydroxide-soluble fraction. (This ratio is included in the results in Table I). This ratio reduction occurred even in patient W. A., in whom the total phenol level was not affected.

From Table I it can be seen that the ether-insoluble phenolic fraction remained at a relatively constant level before and during treatment.

The values for total phenols as well as for the various fractions determined during the remission phase of pernicious anemia show good agreement with the values obtained for normal subjects.^{7, Table I} It is, therefore, apparent that in

*These patients are also included in Table I. Except for B. I. ascorbic acid supplement was continued during the parenteral administration of liver extract.

pernicious anemia in relapse, the excretion of total phenolic compounds and hence of hydroxyphenyl acids is increased above normal levels.

In one patient with pernicious anemia (J. O.) we observed a low excretion of phenols prior to therapy. This individual had a fasting plasma ascorbic acid value of 0.1 mg. per 100 c.c., determined by the method of Mindlin and Butler.⁹ Since ascorbic acid has been shown to have an effect on the oxidation of tyrosine,^{10, 11} 500 mg. of ascorbic acid were given daily for a three-day period and the phenol excretion was measured. The results are shown in Table II. On the second day of ascorbic acid administration there was a definite increase in the hydroxyphenyl acid fraction. Ascorbic acid was also given to two patients with untreated pernicious anemia who had normal plasma ascorbic acid values. No changes in either total phenols excreted or in any fraction thereof were observed following the administration of ascorbic acid (Table II).

DISCUSSION

Effective treatment of patients with pernicious anemia with either liver or stomach preparations results in a decrease in excretion of the phenolic fraction containing hydroxyphenyl acids to a level approximating that obtained in normal subjects. This is evidence that substances concerned with erythrocyte maturation participate, directly or indirectly, in the oxidation of phenolic compounds and hence of the amino acid, tyrosine, beyond the aromatic acid stage.

Three of the known vitamins have been shown to affect tyrosine metabolism in various biologic systems: ascorbic acid,^{10, 11} pyridoxine as pyridoxal phosphate,¹² and pteroylglutamic acid.¹³ Since these vitamins are either absent or present in very small quantities in purified liver extracts,¹⁴ it does not seem possible that the effect of liver extract on phenol excretion can be ascribed to its vitamin content. A more attractive hypothesis is that the antipernicious anemia principle in liver extract activates one or more of these vitamins in some metabolic reaction concerning tyrosine.

In our experiments, administration of ascorbic acid produced no effect on phenol excretion in cases of pernicious anemia where the plasma level of ascorbic acid was normal. In one patient with a low plasma ascorbic acid value and phenolic excretion not increased above normal levels, ascorbic acid administration was associated with an increased phenol excretion. This result is seemingly a contradiction of the well-defined action of ascorbic acid in scorbutic guinea pigs¹⁰ and premature infants¹¹ in lowering the high excretion levels of hydroxyphenyl acid metabolites. However, indications that close metabolic relationships may exist between the liver principle and ascorbic acid are to be found in clinical reports of "anemia of scurvy"¹⁵ and also in reports of vitamin C having a favorable effect on hematopoiesis in pernicious anemia.¹⁶

The results of Levine, Gordon, and Marples¹¹ show that in one of four premature infants, liver extract containing no ascorbic acid resulted in a "transient but definite decrease in hydroxyphenyl compounds." There is a possibility, in view of the experiments reported here, that in this instance the liver principle was the effective agent in reducing phenol excretion. That a deficiency of erythrocyte maturing factors occurs in premature infants is indicated by

reports that such infants often have incompletely developed hematopoietic systems associated with macrocytic anemia.^{17, 18}

This study was completed prior to the investigations concerning pyridoxal phosphate and pteroylglutamic acid in relation to tyrosine oxidation; hence the possible effect of these vitamins on phenol excretion in pernicious anemia patients was not determined.

The evidence for aberrant tyrosine metabolism in pernicious anemia leads to the speculation that some phenolic derivative may directly participate in the erythrocyte developmental processes and that the liver principle may affect red cell maturation by virtue of its action in the tyrosine metabolic cycle to produce this derivative. If the formation of some phenolic derivative is essential in the treatment of macrocytic anemias resulting from a maturation defect, this might explain why liver extract is not effective in treating macrocytic anemia occurring in cases of cirrhosis of the liver¹⁹ since tyrosine is not properly metabolized when liver function is impaired.²⁰

SUMMARY

The treatment of pernicious anemia with liver or stomach preparations decreases the urinary excretion of total phenols by a reduction in the phenolic fraction containing the hydroxyphenyl acids. There is both a relative and an absolute increase in the fraction containing phenol and *p*-cresol. The ether-insoluble fraction remains constant.

The values for both total phenols and hydroxyphenyl acids obtained in pernicious anemia during relapse are greater than those obtained with normal subjects.

No change in phenol excretion levels in pernicious anemia in relapse was observed following administration of ascorbic acid to patients having normal plasma ascorbic acid values. In one patient with a low plasma ascorbic acid value, an increase in phenol excretion levels occurred concomitant with ascorbic acid supplementation.

URINARY PHENOLS IN NORMAL SUBJECTS; EFFECT OF A LIVER EXTRACT

MARIAN E. SWENDBERG, PH.D., BENJAMIN WANDRUFF, M.D., AND
FRANK H. BETHELL, M.D.,
ANN ARBOR, MICH.

THIS paper serves as a comparison study for the preceding communication¹ and reports the fractionation of the urinary phenols excreted by normal subjects and the effect thereon of a liver extract.

METHODS AND MATERIAL

The urinary phenol values were determined according to previously described methods¹ on five normal subjects, medical students and dietitians, before and after the injection of liver extract. Throughout this period, to eliminate variations in phenol excretion due to dietary changes, these subjects were kept on a regulated diet similar to that received by the pernicious anemia patients discussed in the preceding report. This diet, on a 2,400 calorie basis, supplied approximately 85 Gm. of protein, 129 Gm. of fat, and 226 Gm. of carbohydrate. Extra calories were provided when needed to maintain weight by increasing the amount of fat and carbohydrate. The diet was supplemented with 200 mg. of ascorbic acid.

The liver extract, given by intramuscular injection, was a purified preparation containing 15 U.S.P. units per cubic centimeter. Thirty units were given in a single dose.

RESULTS

The values obtained by the fractionation of urinary phenolic compounds under these experimental conditions are shown in Table I.

The daily values, before liver extract administration, for total phenols and for the various fractions show considerable variation among the different subjects but are more constant for each individual. The most constant value for each individual is the ratio of the ether-soluble-bicarbonate-soluble fraction to the ether-soluble-hydroxide-soluble fraction.

The results for the two ether-soluble phenol fractions are in fair agreement, both as to quantity and ratio, with those reported by Schmidt² who used another method.

At the beginning of the fifth day of the diet, 30 units of liver extract (2 c.c.) were given by intramuscular injection. In the subsequent twenty-four-hour period the excretion of total phenols was reduced in three subjects, remained the same in one subject, and was increased in one subject. The total phenols in most cases tended to increase for the remaining two days of the experimental period.

The excretion of ether-insoluble phenols is not affected by liver extract administration, hence changes in total phenols reflect changes in the ether-

soluble phenols. When the two fractions of the ether-soluble phenols are considered separately, the effect of liver extract on their urinary excretion level is similar in all subjects. The bicarbonate-soluble fraction usually shows a considerable reduction, while the hydroxide fraction tends to be increased. As a result, the ratio of the bicarbonate-soluble fraction to the hydroxide-soluble fraction is significantly decreased.

The effect of this one dose of liver extract is transient, and the ratio of the ether-soluble phenolic components begins to increase again on the day following the liver extract supplementation.

*On this day, 30 units of liver extract (15 units per cubic centimeter) were administered intramuscularly.

Values expressed as milligrams tyrosine excreted per twenty-four hours.

DISCUSSION

The ratio of the ether-soluble phenolic components stands out in this study of phenol excretion under controlled dietary conditions as the most constant value obtained. In other studies on the effects of various substances on phenolic excretion, it might therefore be well to give special consideration to the determination of changes in this ratio.

From the data in the preceding paper¹ it has been shown that the ratio of the ether-soluble phenolic compounds in pernicious anemia patients previous to treatment is much increased over that of the normal subjects. Therapy sharply reduces the ratio, but there is considerable day to day variation. The results of this study show that the administration of liver extract to a normal subject exerts a transient reduction in this ratio, but it is not reduced below the lowest ratio obtained in pernicious anemia in remission.

This transient effect of liver extract on the ratio of the ether-soluble phenolic components excreted by normal subjects may be taken as additional evidence that there is a substance present in liver that acts on the processes of phenolic oxidation either directly or indirectly. There are indications that this substance may be the liver antipernicious anemia principle.

The components of the weakly acidic phenolic fraction (phenol and *p*-cresol) are commonly regarded as products of enterogenous metabolism, which are absorbed from the gastrointestinal tract and excreted in the urine.^{2,4} In both normal subjects and pernicious anemia patients there were instances where the excretion of this phenolic fraction was increased by liver extract injections. This increase would appear to be the result of an endogenous metabolic process, presumably an effect secondary to the increased oxidation of hydroxyphenyl acids.

SUMMARY

Values for the urinary excretion of various phenolic fractions from normal subjects on a regulated diet have been reported. The most constant value was the ratio for the ether-soluble phenols of the bicarbonate-soluble fraction to the hydroxide-soluble fraction.

When 30 units of liver extract were given, although the amount of total phenols excreted showed no consistent variation, there was a temporary reduction in the ratio of the ether-soluble phenolic components, due both to a decrease in the bicarbonate-soluble fraction containing the hydroxyphenyl acids and an increase in the hydroxide-soluble fraction.

THE POTENCY OF THE U. S. P. REFERENCE STANDARD FOR VITAMIN D

WALDEMAR DASLER, CLIFFORD D. BAUER, AND MARTHA VAN NOSTRAND
CHICAGO, ILL.

ARNOLD¹ has recently published data which indicate that calciferol (vitamin D₂) has a potency of 49.7 ± 2.1 U. S. P. units per microgram in terms of the present U. S. P. reference standard for vitamin D. From this he concludes that the "U. S. P. reference cod liver oil No. 2 has less than its generally accepted potency." If this conclusion is found to be valid, medicinal vitamin D preparations which are assayed by the U. S. P. technique must also be lower in potency than the assays indicate.

Fritz, Hooper, and Moore,² in connection with the Association of Official Agricultural Chemists' chick assay of vitamin D₃, have previously called attention to the possibility that the U. S. P. reference standard may be deteriorating. In this connection it may also be pertinent to call attention to the fact that the vitamin A potency of the U. S. P. reference cod-liver oil No. 2 as determined by Callison and Orent-Keiles³ was lower than its originally assigned value.⁴

Gridgeman^{5, 6} has reported the potency of vitamin D₂ to be 36 I.U. per microgram and that of vitamin D₃ to be 46.4 I.U. per microgram. Although Gridgeman compared calciferol to the international standard, while Arnold¹ used the U. S. P. reference standard, Gridgeman's values strike a discordant note, since an overwhelming weight of evidence indicates that vitamin D₂ and D₃ have equal antirachitic activity for the rat. Remp and Marshall,⁷ for instance, found vitamins D₂ and D₃ to be equal in potency for the rat. The results of a collaborative study in which nine laboratories participated were reported by Coward⁸ and showed vitamins D₂ and D₃ to have equal potency for the rat. More recently, Huber and Barlow⁹ have stated emphatically that the two vitamins behave exactly alike as to potency in the rat.

In 1943 Huber and Barlow⁹ reported that, on the basis of over 400 satisfactory assays, the antirachitic value of calciferol was well over 40 U. S. P. units per microgram. Some time ago we also observed that samples of calciferol, when compared with the U. S. P. reference standard, consistently had an apparent potency at least 10 to 20 per cent higher than 40 U. S. P. units per microgram. We have therefore repeatedly assayed fresh samples of calciferol from three different sources against the U. S. P. reference cod-liver oil No. 2. The calciferol was dissolved in corn oil and assayed on rats of the Sprague-Dawley strain by the U. S. P. technique.¹⁰ The results are given in Table I.

The initial assays seemed to indicate that the potency of the isolated sample was higher than that of the others. All subsequent assays, however, indicate that the potency of each of the three samples was over 48 and under 52 units per microgram.

DISCUSSION AND CONCLUSIONS

The antirachitic potency of the U. S. P. reference cod-liver oil No. 2 was originally determined by assay against the international standard for vitamin D.⁴ The U. S. P. unit of vitamin D was, in fact, defined as "equal, in antirachitic potency for the rat, to one International Unit of Vitamin D as defined and adopted by the Conference of Vitamin Standards of the Permanent Commission on Biological Standardization of the League of Nations in June of 1931."¹² The antirachitic potency of pure calciferol, therefore, should be the same whether expressed in international units or in U. S. P. units. This appears not to be the case, at least when the U. S. P. standard currently being distributed is used.

The potency of calciferol is recorded in the report of the Second Conference on Vitamin Standardization of the League of Nations¹³ as 40 I.U. per microgram. This value was confirmed in a comprehensive study by Anderson, Bacharach, and Smith¹⁴ and by the collaborative study reported by Coward.⁸

Older values obtained by comparative assays against an earlier U. S. P. reference oil^{7, 15} indicate that the potency of calciferol at that time was also 40 U. S. P. units per microgram in terms of the then current U. S. P. standard.

The discrepancy between the more recent and the older values for the potency of calciferol might be explained by the assumption that the samples of calciferol more recently available were of a higher degree of purity than the samples with which the older work was done. When the constants of the calciferol used in the aforementioned collaborative study,⁸ of the calciferols studied by Anderson, Bacharach, and Smith,¹⁴ and of the "pure calciferol" for which specifications were given in the report of the Second International Vitamin Conference¹³ are compared with the constants of the samples of calciferol used by Huber and Barlow,⁹ Arnold,¹ and ourselves, it appears that the earlier samples of calciferol were equally as pure as those used more recently.

The only reasonable explanation for the findings of Huber and Barlow,⁹ Arnold,¹ and ourselves, therefore, appears to be that the U. S. P. reference standard for vitamin D is below its stated potency. These results and the findings of Callison and Orent-Keiles³ with relation to the vitamin A potency of the standard strengthen the hypothesis of Fritz and co-workers² that the reference standard is deteriorating. It may therefore be advisable to re-evaluate the potency of the U. S. P. reference standard for vitamin D and to re-examine

recent data obtained by comparative assays with this standard. The substitution of a primary standard for the cod-liver oil standard should be considered. We concur in the recommendations of Arnold¹ and of Waddell and Kennedy¹⁶ that pure, crystalline vitamin D₃ be adopted as the reference standard for vitamin D preparations.

EFFECT OF TYROSINE, TRYPTOPHANE, AND THIOURACIL ON MELANURIA

ABRAHAM G. WHITE, M.D.
NEW YORK, N. Y.

THERE has been much speculation on the origin of melanin and melanogen pigments widely distributed in nature and found in pigmented tumors. Eppinger¹ concluded from feeding experiments with tryptophane and tyrosine in a case of melanosarcoma that tryptophane was the precursor of melanogen. Raper² demonstrated that tyrosine was converted to melanin by tyrosinase. Paschkis and co-workers³ found that thionracil inhibited the *in vitro* formation of melanin by tyrosinase.

The purpose of the present investigation was to repeat the experiments of Eppinger and to determine the effect of thiouracil upon the melanin metabolism of a 47-year-old white woman with a melanosarcoma presumably arising from the adrenal gland and metastasizing throughout the body, as revealed by post-mortem examination. In the course of these studies, an improved method for the quantitative determination of urinary melanogen was developed.

METHODS

The urinary melanogen was determined as follows (modification of Thormählen reaction⁴):

To 5 c.c. of urine, 5 c.c. of a 33 $\frac{1}{3}$ per cent (w/v) solution of sodium nitroprusside were added, followed by 5 c.c. of a 10 per cent (w/v) sodium hydroxide solution, and then by 5 c.c. of a 33 $\frac{1}{3}$ per cent solution of acetic acid. The solution was made up to 500 c.c. with water. Five cubic centimeters of a standard indole solution (containing 0.5 mg. per cubic centimeter) were treated similarly. An A. C. model Fisher electrophotometer with a 650 A filter (with a wave length range of 600 to 700 m μ) was used for the colorimetric comparisons.

Calibration studies with aqueous indole solutions indicated a high degree of conformity of the Thormählen reaction with Beer's law (Fig. 1). Quantitative recovery of added indole from urine was close to 100 per cent in the range of the patient's urinary "melanogen" concentrations (35 to 50 mg. per cent), as shown in Table I.

TABLE I. URINARY INDOLE RECOVERY EXPERIMENTS

ACTUAL CONCENTRATION (MG. %)	OBSERVED CONCENTRATION (MG. %)	AVERAGE OBSERVED CONCENTRATION (MG. %)	PER CENT RECOVERY
15	16.5	16.6	110.7
	16.6		
30	33.4	32.9	109.6
	32.5		
50	49.2	48.4	96.8
	47.5		
65	64.1	63.6	97.9
	63.0		

Fig. 1.—Electrophotometric scale reading (scale A) equals $100 \times (2 - \log \text{ per cent transmission})$.

A, C = 1.5 GMS. d-1-TRYPTOPHANE FED
 B 2.0 GMS. l-TYROSINE FED

Fig. 2.—The amino acids were fed at A, B, and C at the beginning of the respective twenty-four hour periods. No melanogen determinations were performed on the third and tenth days.

Rothman⁵ reported that the Thormählen test is negative in indicanuria. I have also observed one subject with indicanuria whose urine yielded a negative nitroprusside reaction. Indican, therefore, is not likely to be confused with melanogen.

EXPERIMENTAL

Our patient was fed 1.5 Gm. of dl-tryptophane, on each of two days, and 2.0 Gm. of l-tyrosine, on another day, as aqueous suspensions flavored with lemon juice.

The results are presented in Fig. 2.

In control studies of twenty-four hour urine specimens collected from ten hospital patients without melanomas and on a regular hospital diet, the Thormählen reaction was negative. In addition, random urines from about 100 patients with diverse diseases yielded a negative Thormählen reaction. Urines collected during the twenty-four hours following the feeding of 1.5 Gm. of dl-tryptophane to each of five normal men and 2.0 Gm. of l-tyrosine to each of five others failed in all cases to give the Thormählen reaction.

After the tyrosine and tryptophane feeding experiments were completed, 0.2 Gm. of thiouracil was administered to our patient three times a day. On the sixth day of drug administration the urine, which had previously been brownish-black, began to lighten in color, and by the eighth day the color approximated that of normal urine. Daily observations were made on each sample for one week or more. These normally colored urines did not darken through the week or more of observation after voiding, even though they were exposed to light (conditions under which melanogen is converted to melanin). The drug was discontinued on the tenth day. Three days thereafter the urine again became black. The patient died at this point, and the experiment could not be repeated.

Thiouracil did not affect the urinary color directly. When 0.2 Gm. of it (several hundredfold excess) was added to 10 c.c. of black urine and incubated at 37° C. for twenty-seven hours, no change in color was observed.

DISCUSSION

Investigators studying patients with melanosarcoma and melanuria have been limited by the fact that such patients do not live very long after the melanuria is detected; in this respect our patient was no exception.

In our patient both tyrosine and tryptophane increased the melanogen excretion slightly above the mean daily output of 122.4 ± 30.0 mg., expressed as "indole," in the control period. After tryptophane was fed 154.9 and 156.4 mg. were excreted; after tyrosine, 169.4 milligrams. These results do not confirm the difference in the behavior of the two amino acids found by Eppinger. It should be noted that his patient was vomiting when she was fed tyrosine, which may account for his failure to observe any increase in the urinary melanogen excretion afterward.

A possible mechanism of thiouracil action in our patient is the inhibition of tyrosinase activity in the tumor cells.

Lynn and De Marie,⁶ studying the melanophores of tadpoles, and Juhn,⁷ the feathers of brown Leghorn capons, observed decreased pigmentation after thiouracil, but these reactions apparently did not involve the inhibition of tyrosinase.

After this study had been completed, Sugiura⁸ reported that daily ingestion of 15 mg. of thiouracil by mice had no inhibitory effect on the growth of transplanted Harding-Passey mouse melanoma.

SUMMARY

1. The feeding of tyrosine and tryptophane to a patient with melanoma-sarcoma and melanuria resulted in a small, possibly significant, increase in the urinary excretion of melanogen.

2. Thiouracil administration caused the urine to change from black to a normal color.

3. The color reverted to black when the drug was discontinued.

4. A possible mechanism of the thiouracil action is the inhibition of melanin formation in the tumor cells.

I wish to extend my thanks for the advice and encouragement given by Dr. Louis Leiter, Chief of the Medical Division, Montefiore Hospital.

ALLOXAN DIABETES IN THE MOUSE

ARNOLD LAZAROW, PH.D., M.D.
CLEVELAND, OHIO

ALTHOUGH the effect of alloxan has been studied on a large number of species (rabbit,^{2, 4} dog,⁵ rat,^{5, 9} monkey,³ man,⁴ frog,¹⁴ and duck¹³), to date no reports have been noted on the production of diabetes in the mouse. Inasmuch as it is desirable to use a small diabetic animal when working with expensive materials, as would be the case with tracer substances, this study on mice was undertaken. We were interested in studying the effect of diphosphopyridine nucleotide (D.P.N.) on the action of alloxan and consequently turned to mice to conserve materials. Diphosphopyridine nucleotide and alloxan have been reported to compete with each other in a yeast apozymase system.¹⁰ Since the alloxan inhibition of this enzyme system can be reversed by adding large quantities of diphosphopyridine nucleotide, it was thought desirable to test the effect of diphosphopyridine nucleotide on the production of diabetes with alloxan.

METHOD

Alloxan monohydrate was injected intravenously into the tail vein of the mouse. The mouse was immobilized in a glass cylinder. The tail protruded through a notch in the rubber stopper used to plug one end. An air hole at the opposite end served for ventilation. The entire mouse was warmed on the heating coil of a 56° C. oven for one to several minutes. The induced vasodilatation in the tail facilitated the intravenous injection. A 26-gauge hypodermic needle was used, and blood was drawn into the syringe before starting the intravenous injection. The alloxan was injected as a 1 per cent solution in distilled water. Blood samples (0.05 c.c.) were removed forty-eight hours later by cutting the tip of the tail (after warming the mouse), and the sugar was determined by the Folin-Malmros micromethod.⁷

The diphosphopyridine nucleotide preparation* used for the injections was only 20 per cent pure and was injected in doses of 750 mg. per kilogram intravenously. A separate vein was used for the alloxan which was injected two to five minutes following the diphosphopyridine nucleotide injection.

DATA

Table I shows the effect of injecting various doses of alloxan intravenously in the mouse. The animals were allowed food and water, ad libitum, before and during the experiment. When no alloxan was administered the blood sugar levels of seven of eight mice varied between 169 and 180 mg. per 100 c.c.; only one mouse had a blood sugar value slightly greater than 200 mg. per 100 cubic centimeters. The average forty-eight hour blood sugar is tabulated for the various doses of alloxan used. The average forty-eight hour blood sugar values given in Table I also include those of animals which did not show any blood

From the Department of Anatomy, School of Medicine, Western Reserve University.

sugar response to alloxan. The incidence of diabetes can be judged by the number of mice with forty-eight hour blood sugar values greater than 250 mg. per 100 cubic centimeters. Mice with mild or questionable diabetes are included in the group whose forty-eight hour blood sugars are greater than 200 mg. per 100 cubic centimeters.

TABLE I. EFFECT OF ALLOXAN INJECTION (INTRAVENOUS) ON MICE

NUMBER OF MICE	DOSE OF ALLOXAN (MG./KG.)	AVERAGE 48-HOUR BLOOD SUGAR	% OF MICE WITH 48-HOUR BLOOD SUGAR (> 200 MG./100 C.C.)	% OF MICE WITH 48-HOUR BLOOD SUGAR (> 250 MG./100 C.C.)
8	0	178	12	0
2	30	203	50	0
7	40	358	71	43
4	50	372	100	50
8	75	464	100	88
2	100	600	100	100

At a dose of 40 mg. per kilogram, three of seven mice had forty-eight hour blood sugar values ranging between 504 and 644 mg. per 100 cubic centimeters. Two showed forty-eight hour blood sugar values slightly greater than 200 mg. per 100 c.c., and the remaining two showed forty-eight hour blood sugar values slightly under 200 mg. per 100 cubic centimeters. Clearly, then, only 43 per cent of seven animals developed significant diabetes at an alloxan dose of 40 mg. per kilogram. When the dose of alloxan was increased to 75 mg. per kilogram, seven of eight mice showed blood sugar values, at forty-eight hours, ranging between 436 and 596 mg. per 100 cubic centimeters. Only one of eight mice showed a blood sugar value at forty-eight hours of 240 mg. per 100 cubic centimeters. Thus, alloxan in doses of 75 mg. per kilogram produced diabetes in nearly all of the mice injected.

Two mice were injected intravenously with diphosphopyridine nucleotide in doses of 750 mg. per kilogram. Inasmuch as the diphosphopyridine nucleotide was only 20 per cent pure, this corresponds to a dose of 150 mg. per kilogram of pure diphosphopyridine nucleotide. Alloxan was injected in doses of 75 mg. per kilogram two to five minutes following the diphosphopyridine nucleotide administration, separate veins being used for each intravenous injection. Blood sugars were determined at forty-eight hours. The two animals receiving diphosphopyridine nucleotide plus alloxan had forty-eight hour blood sugars of 518 and 626 mg. per 100 cubic centimeters. Consequently, no effect could be attributed to the diphosphopyridine nucleotide injection.

DISCUSSION

It will be noted that mice respond to the intravenous injection of alloxan. The dose of alloxan required to produce diabetes in mice seems to be somewhat greater than that required for rats. For in the latter animal, the intravenous injection of alloxan in doses of 40 mg. per kilogram produced diabetes in 95 per cent of the animals injected.¹² As has been previously reported,¹² when alloxan is injected intravenously much smaller doses are required to produce a

given level of diabetes than is the case when the alloxan is injected intraperitoneally. This has also been found true in the mouse.

The amounts of diphosphopyridine nucleotide and alloxan used in these mouse experiments are of the same order of magnitude as the concentrations used by Kensler and co-workers¹⁰ in studying a yeast apozymase system. In these latter experiments an apozymase preparation was suspended in buffer pH 6.5 in the presence of magnesium chloride, glucose, and hexose diphosphate. When the alloxan concentration was 2.2×10^{-4} molar and the diphosphopyridine nucleotide concentration was 15 μg per 4 c.c., the enzyme activity was inhibited to the extent of 92 per cent. However, when the alloxan concentration was kept constant and the diphosphopyridine nucleotide concentration was increased to 525 μg per 4 c.c., only 7 per cent inhibition took place. A diphosphopyridine nucleotide concentration of 525 μg per 4 c.c. corresponds to a concentration of 133 mg. per liter, whereas an alloxan concentration of 2.2×10^{-4} molar corresponds to a concentration of 35 mg. per liter. In the mouse experiments the alloxan was injected in doses of 75 mg. per kilogram to insure diabetes. However, the concentration of alloxan that is actually acting on the mouse cannot be accurately determined. At the pH of the body (7.4), 50 per cent of the alloxan present is converted to a nondiabetogenic compound, alloxonic acid, within the first three minutes.¹¹ The rate of conversion at pH 6.5 (the conditions used in the apozymase experiments) would be expected to be much less, although the precise rate has not been determined. Alloxan is also reduced to dialuric acid by glutathione.¹ However, the rate of inactivation of alloxan by glutathione in the intact mouse or in the isolated apozymase system studied by Kensler and co-workers¹⁰ cannot be accurately determined. Thus, although the conditions in the mouse experiments cannot be accurately compared with those used in the apozymase system, the amounts of alloxan and diphosphopyridine nucleotide used were of the same order of magnitude. The fact that no protection was observed cannot be taken as evidence that a competition between alloxan and diphosphopyridine nucleotide does not take place in the body, inasmuch as the latter compound may not be able to penetrate the cell membrane; although one might suspect that with beta cell degeneration taking place, the permeabilities might also be changed sufficiently to permit such a compound to penetrate. The presence of phosphatase in the blood may also have played a role in destroying the diphosphopyridine nucleotide administered.

SUMMARY

Alloxan, injected intravenously, produced diabetes in the mouse. With a dose of 75 mg. per kilogram seven of eight animals showed a forty-eight hour blood sugar value ranging between 436 and 596 mg. per 100 cubic centimeters. In two experiments using a large dose of diphosphopyridine nucleotide, injected immediately preceding a diabetogenic dose of alloxan, the course of the diabetes was not altered.

BACTEREMIA AND ACUTE MENINGITIS DUE TO *ALCALIGENES FAECALIS*

A CASE REPORT

LUTHER L. TERRY, M.D.,* BALTIMORE, Md., JOHN K. MCBANE, M.D.,† SANTA CRUZ, CALIF., AND KATHRYN F. DEAN, M.T.,‡ BALTIMORE, Md.

ALCALIGENES faecalis is generally considered to be saprophytic and non-pathogenic. However, it seems well established that this organism can produce disease. A review of the literature reveals that *A. faecalis* has been associated with a variety of clinical conditions. Anderson¹ cultured it from the blood of two patients who exhibited a syndrome simulating rheumatic polyarthritis. The organism was isolated from the blood of a patient with acute hepatitis and jaundice by McIntyre.² An *Alcaligenes* type of bacillus was cultured from the blood of a patient with a typhoidlike state by Hazen and Mortillaro,³ and from the blood of three patients with gangrenous appendicitis by Weiss.⁴ It was thought to be the cause of death in a patient with protracted sepsis reported on by Goldberg.⁵ The organism has been cultured from gallstones⁶ and renal calculi.⁷ It has been considered the pathogenic agent in certain types of infant summer diarrhea⁸ and the cause of a few cases of adult enterocolitis.⁹

There are only four cases reported in which *A. faecalis* was responsible for meningitis. Voorhies and Wilen¹⁰ described a case with *A. faecalis* bacteremia and meningitis which apparently responded to sulfadiazine therapy. Spray and Hawk¹¹ reported a case of meningitis following otitis media. Mason¹² reported a meningitis complicating a meningocele, and Gatewood¹³ described a case of meningitis following a craniotomy.

The case reported herein apparently represents the fifth case of meningitis due to *A. faecalis* to be described in medical literature.

CASE REPORT

A. F. S., a 42-year-old merchant seaman, was admitted to the hospital on May 11, 1946, complaining of fever and weakness. He had been well until four days previously when he first noted intermittent periods of chilliness and fever. The following day he began to cough and noted general malaise and aching over the entire body. The symptoms gradually increased in severity and he vomited on two or three occasions. A few hours prior to admission he began perspiring profusely and noted extreme weakness. The remainder of the history was non-contributory.

Physical Examination.—On admission physical examination revealed a well-developed and well-nourished male who appeared prostrated. Temperature was 37.2° C. (99° F.); pulse 82; and blood pressure, 132/72. There was mild hyperemia of the pharynx and a few scattered crackling râles were heard over the lung fields.

From the Medical and Pathology Services, U. S. Marine Hospital, Baltimore, Md.
Received for publication, July 19, 1947.

†Formerly Senior Assistant Surgeon, United States Public Health Service.

‡Bacteriologic Technician.

Hospital Course.—A tentative diagnosis of atypical pneumonia was made upon admission but the chest x-ray was clear. The patient was treated symptomatically but remained restless and complained of headache and some vertigo upon standing. On the third hospital day the headache became more intense, and slight rigidity of the neck was noted for the first time. The temperature which had been normal except during the first few hours in the hospital rose to 38° C. (100.5° F.). Lumbar puncture revealed a bloody fluid under 210 mm. of water pressure. It was not cultured. The patient was not relieved by the spinal puncture but continued to complain of severe headache and vomited frequently. The temperature remained about 37.7° C. (100° F.).

On the fourth hospital day the spinal fluid was still bloody and under slightly increased pressure. The patient remained conscious and oriented but complained of headache almost continually and vomited frequently. On the fifth hospital day the laboratory reported growth of a motile gram-negative bacillus with slight tendency to bipolar staining. The patient was then started on streptomycin intramuscularly (2.0 Gm. daily divided into equal doses every three hours) and intrathecally (0.1 Gm. daily) and sulfadiazine. The blood sulfadiazine level was maintained about 10.0 mg. per cent. Streptomycin blood levels were not done.

The organism recovered from the spinal fluid on four successive days and from one blood culture was a motile gram-negative rod that did not produce acid or gas on carbohydrate media, produced an alkaline reaction in litmus milk, reduced nitrates to nitrites, and was indol negative. It was identified by our laboratory as *A. faecalis*. Subcultures from the spinal fluid and blood were also sent to the Bureau of Bacteriology of the Maryland State Department of Health and the identification of the organism was confirmed. The organism was not inhibited by 16 µg per milliliter of streptomycin or by 10 mg. per milliliter of sulfadiazine.

Following the institution of therapy with streptomycin and sulfadiazine the temperature rose over the next two days, reaching 39.5° C. (103.1° F.) on the seventh hospital day. The patient's general condition was otherwise unchanged. However, during this time the spinal fluid changed from bloody to cloudy fluid containing about 1,000 cells and cultures became negative for *A. faecalis*. A blood culture taken just before treatment was started was positive for *A. faecalis*. About the fifth day of treatment the temperature, which had been ranging about 39.5° C. (103.1° F.), began to drop by lysis. The headache decreased in intensity and the patient appeared greatly improved. The subsequent clinical course was one of gradual, progressive recovery.

The intrathecal streptomycin was discontinued after nine days but the intramuscular streptomycin was continued for thirteen days and the sulfadiazine for seventeen days.

Since no portal of entry of the infection was obvious, the patient was carefully surveyed prior to discharge from the hospital. Several routine urine analyses were negative and intravenous pyelogram was normal. *A. faecalis* could not be recovered from several stool cultures. Proctoscopic examination showed no abnormalities. Gastrointestinal series showed slight irregularity of the duodenal cap, but no ulcer could be identified. There was slight spasticity of the sigmoid colon on barium enema, but no diverticuli or other abnormalities could be found.

Laboratory Findings.—The most significant laboratory findings are shown in Fig. 1. Other findings were as follows: On admission the hemoglobin was 14.2 Gm.; white blood count, 16,200 per cubic millimeter with 69 per cent neutrophils (14 stabs), 3 per cent monocytes, 6 per cent eosinophiles, and 22 per cent lymphocytes. Blood Kline and Kahn tests were negative. Urinalysis showed an alkaline reaction and no significant findings. A heterophile antibody titer was 1:14. Agglutination titers were: typhoid "O," 1:20; typhoid "H," 1:80; paratyphoid A, 1:20; paratyphoid B, 1:40; *Brucella abortus*, negative; and proteus "OX19," negative.

Upon discharge the patient's white blood count was 9,200; hemoglobin, 13.2 Gm.; urine, negative; the spinal fluid and blood cultures showed no growth. Specific agglutinins for *A. faecalis* were not present in the blood at any time.

Follow-up Examination.—The patient was readmitted to the hospital on Nov. 2, 1946, for follow-up examination, approximately five months following discharge. At that time he stated that he was feeling well. He complained only of occasional frontal headaches and mild

vertigo. Complete physical examination, including detail neurological survey, was completely negative. Lumbar puncture revealed a clear fluid under normal pressure and with normal dynamics. The cell count was 0 and the globulin was negative and there was no growth on culture.

The patient was again observed on May 20, 1947, about one year after the illness. Complete neurological examination was again essentially normal.

Fig. 1.—Summary of pertinent clinical and laboratory data on a case of *A. faecalis* bacteremia and meningitis.

COMMENT

The isolation of *A. faecalis* in pure culture four times from the spinal fluid and once from the blood seems to establish a case of bacteremia and acute meningitis due to this organism. Though *A. faecalis* is fairly frequently encountered in stool cultures, it is generally not thought capable of producing disease. A few instances to the contrary have been cited herein. This case serves to illustrate that *A. faecalis* can produce disease under certain circumstances. Unfortunately we are unable to attribute this pathogenicity to a lack of resistance on the part of the host or to a proved increased virulence of this particular strain or organism. There was no known event to suggest a decrease in resistance of the host, and animal virulence tests were not done with the cultures of *A. faecalis*.

The part therapy played in the recovery of this patient is also uncertain. The in vitro sensitivity tests on the organism revealed that growth was not inhibited by 16 μ g per milliliter of streptomycin or by 10 mg. per milliliter of sulfadiazine. Both of these figures indicate considerable resistance on the part

of the organism, and generally one does not expect a favorable response to treatment under such circumstances. The slow clinical response in this case casts considerable doubt relative to the effect of either streptomycin or sulfadiazine. However, there may have been some synergistic activity between the two. One would not have expected recovery without some specific therapeutic effect, but spontaneous recovery cannot be disproved.

Textbooks of bacteriology express doubt relative to the production of specific agglutinins for *A. faecalis* in patients with infections due to this organism. However, Wyatt¹⁴ and Stuart, Thompson, and Krikorian⁷ have found agglutinins present in low titer. The case reported by Voorhies and Wilen¹⁰ did not show agglutinins. They were not demonstrable in this case.

SUMMARY

A case of acute bacteremia and meningitis due to *A. faecalis* is described. Despite high in vitro resistance of the organism to both streptomycin and sulfadiazine alone, the patient recovered under treatment with these two agents; synergistic activity may have been present. No preceding infection or port of entry for *A. faecalis* could be demonstrated. Agglutinins for *A. faecalis* could not be demonstrated in the blood after recovery. Follow-up examinations five and twelve months after the onset of illness failed to reveal any abnormalities.

LABORATORY METHODS

THE THYMOL TEST OF MACLAGAN

STANDARDIZATION AND ADAPTATION TO THE EVELYN PHOTOELECTRIC COLORIMETER

HECTOR DUCCI, M.D.

SANTIAGO, CHILE

IN THE course of work with the thymol test of MacLagan,^{1, 2} started early in 1945, it soon became apparent that the visual estimation of turbidity was not convenient for precise investigation.

Standards prepared according to King and Haslewood,³ obtained from two different sources and also from our laboratory, were slightly different. Moreover, comparison in the case of lipemic or deeply icteric sera was difficult or impossible.

In an attempt to obviate these disadvantages, a blank prepared with serum and 0.85 per cent sodium chloride (1 to 60 volumes) was introduced for each determination. Although this modification made easier the measurement of the turbidity of sera with a high bilirubin or fat content, it did not eliminate the errors inherent to visual methods of nephelometric analysis.

In order to use the photoelectric colorimeter for the turbidimetric determinations, an easily reproducible and stable calibration was necessary. Serum plus sulfosalicylic acid and barium sulfate were found unsuitable as standards, due to great variation in the results obtained. Finally a copper sulfate solution was adopted for calibration; it is easily prepared and gives in different experiments almost identical readings at 660 μ .

In this study the Evelyn photoelectric colorimeter has been used.

EXPERIMENTAL

Choice of Filter.—

Measurements at 660 μ are very convenient, due to little interference with bilirubin and hemoglobin light absorptions and due to enough sensitivity for turbidity. Shank and Hoagland⁴ have emphasized these points.

Calibration.—

Serum With Known Protein Content: The turbidity developed when 3 per cent sulfosalicylic acid is added to diluted serum is the method recommended to check the gelatin standards in the thymol test.²

Sera of known protein concentration (Kjeldahl in duplicate) were diluted with 0.85 per cent sodium chloride, so as to obtain solutions corresponding from

With a grant from the Rockefeller Foundation.
From Section A of Medicine (Dr. Hernan Alessandri), Hospital del Salvador.
Received for publication, May 27, 1947.

8 to 200 mg. of protein per cent; that is to say, from 0.8 to 20 thymol units. Three volumes of 3 per cent sulfosalicylic acid were added to each tube, and the readings were made in the Evelyn photoelectric colorimeter with No. 660 filter.

The results obtained with different sera and also with the same serum at different moments were very variable, as shown in Fig. 1.

This inconsistency of the turbidimetric measurements of serum protein has also been demonstrated for different albumin preparations by Shank and Hoagland.⁴

THYMOL UNITS

Fig. 1.—Calibration with diluted serum plus sulfosalicylic acid. Only three illustrative examples are reproduced. Values are expressed in thymol units (milligrams of protein divided by ten).

Barium Sulfate: Shank and Hoagland⁴ have advocated a barium sulfate standard for the calibration of the spectrophotometer in the thymol test.

When this procedure was first employed very high values were found, but this was due to a typographic error in the original paper. The barium chloride solution is 0.0962 M (2 per cent) instead of 0.0962 N (1 per cent), according to the correction in the reprints.

Calibration with the barium sulfate standard is also variable, even if the same reagents and the same temperature are used, as shown in Fig. 2. This is probably due to different size of the precipitate particles and renders this method inconvenient for photoelectric calibration.

Thymol Purity.—

The chemical purity of the thymol crystals has certain importance in the turbidity values obtained. Using two different brands, discrepancies were found in a great number of sera studied, as shown by the typical examples given in Table I. The reagents were prepared with the same chemicals and precautions, except for the thymol crystals.

Blank.—

Even if the No. 660 filter is used in the photoelectric measurements, it is convenient to run a serum blank to eliminate the influence of natural opalescence,

TABLE I

SERUM	THYMOL CRYSTALS FROM	
	FRITZCHE BROTHERS, INC. (NEW YORK) (UNITS)	MEECK (DARMSTADT) (UNITS)
1	6.6	7.6

8	11.3	11.56

Fig. 2.—Calibration with barium sulfate. Only three illustrative examples are reproduced. Values are expressed according to Shank and Hoagland,⁴ and in thymol units.

hemolysis, or high bilirubin content completely. This is shown in the typical examples given in Table II where readings using thymol buffer and serum plus saline as blanks, are compared.

The use of a serum-saline blank depends on having a clear thymol buffer. In our experience it has never become opalescent or turbid on standing, but this can happen under certain conditions apparently related to climate. Watson,⁵ for instance, stated: "The thymol buffer solution is not as constant as one might wish; its turbidity varies a little from batch to batch, and from time to time. We find that on standing it becomes visibly more turbid over a period of weeks, and that this cannot be removed by filtration." Schloss⁶ also refers to variations of the thymol reagent.

If one has to work with a more or less turbid thymol buffer, it is more convenient to use it as a blank instead of serum-saline.

After many trials, the following calibration has been adopted. It is very easy to perform and, although it is purely empirical, the values obtained are

TABLE II

SERUM	BLANK	
	THYMOL BUFFER (UNITS)	SERUM PLUS SALINE (UNITS)
1	4.3	5.1
2	2.96	1.39
3	2.13	2.5
4	6.2	5.1
5	12.06	11.56
6	3.2	2.89
7	3.5	2.8
8	5.0	3.8

similar to those reported by MacLagan with the visual estimation. A blue solution has been used since the readings for turbidity are taken with a red (No. 660) filter.

METHOD

Calibration.—A 5 per cent aqueous solution of copper sulfate ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$) is prepared and filtered if necessary. To 2 ml. in an Evelyn tube, 8.5 ml. of distilled water are added. From this diluted solution, 3 ml. and 1.5 ml. are placed in a second and third Evelyn tube, respectively, and the volume is taken up in both to 6 ml. with distilled water. The readings are made in the Evelyn colorimeter, using the No. 660 filter, the 6 c.e. aperture, and bright light, with distilled water as a blank. The equivalence of the standards in thymol units and a typical example of calibration are shown in Table III.

TABLE III

2 ML. OF 5 PER CENT $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ + 8.5 ML. OF DISTILLED WATER	DISTILLED WATER	UNITS	G
6 ml.	-	20	54'
3 ml.	3 ml.	10	73
1.5 ml.	4.5 ml.	5	85

The straight line relationship between the optical density of the standards is shown in Fig. 3. For convenience, a table with the correspondence between G values and thymol units is reproduced (Table IV).

The intensity of the blue color is not dependent upon the brand of copper sulfate or the time elapsed between preparation of the solution and colorimetric readings. Salts from three different sources (Baker; Schering, Kahlbaum; and Merck, Darmstadt) gave identical G values soon after preparation or after standing overnight at room temperature.

Procedure.—The thymol buffer is prepared as described by MacLagan,² using reagent grade thymol crystals. As the final pH of the solution somewhat varies, it is convenient to adjust it to 7.8. The buffer is stored at a temperature over 20° C., as recommended by MacLagan. On standing over a long period, the thymol solution may show a small amount of precipitate at the bottom of the flask; although it could still be used, it is better to discard it.

In each of two Evelyn tubes, 0.1 ml. of serum is measured; 6 ml. of thymol buffer and 6 ml. of 0.85 per cent sodium chloride are added, respectively. After

Fig. 3.—Calibration with copper sulfate. Values are expressed in thymol units.

standing for one-half to one hour, readings are taken in the Evelyn colorimeter (No. 660 filter, 6 c.e. aperture, and bright light), using the serum-saline tube as a blank. If the thymol solution is more or less turbid, a buffer blank is substituted for the serum-saline one. The value in thymol units is obtained from Table IV. It is convenient to shake the serum-thymol tube gently before placing it in the colorimeter, for some sedimentation may occur even in this short time.

After completion of the readings, the content of the serum-thymol tube is placed in a small Pyrex tube and left undisturbed overnight to allow observation of the amount of precipitate formed. This is graded from 0 (absent) to 3 plus; no 4 plus value has been used for some of the precipitate remains adherent to the walls of the tube, even with strongly positive sera.

NORMAL AND PATHOLOGIC VALUES

Using the method described, the range found in 100 apparently normal subjects was from 0.4 to 4.0 units.⁷⁻⁹ In only five of these cases some precipitate occurred after eighteen to twenty hours; four were recorded as 1 plus, and one as 2 plus.

In 152 of 170 cases of hepatocellular jaundice studied in the acute phase of the disease, the thymol turbidity test was over 4 units (89.4 per cent). Of the total, 111 were examples of infectious (sporadic) hepatitis, and fifty-nine, of cirrhosis with clinical icterus (thirty-four proved by punch biopsy, peritoneoscopy, or post-mortem examination). In 113 of these same cases (66.4 per cent) some degree of flocculation was observed.⁹

The thymol turbidity test was negative in twenty-two of thirty-five cases of obstructive jaundice (62.8 per cent) in which the diagnosis was confirmed by operation, necropsy, or punch biopsy; thirteen cases were due to cancer, nineteen to coledocolithiasis, and three to benign stricture of the common duct. Flocculation was negative in thirty; three of the positive results were 3 plus, and two, 2 plus.⁹

DISCUSSION

The thymol test of MacLagan is a useful complement to the laboratory study of diseases of the liver and bile ducts, as demonstrated by various reports.^{2, 4, 8-13}

A drawback of the test is the visual estimation of turbidity advocated by MacLagan.^{1, 2} Moreover, the gelatin standards of King and Haslewood³ are not easy to prepare and vary in opalescence when they are obtained from different sources.

Albumin plus sulfosalicylic acid and barium sulfate have been demonstrated unsuitable for calibration on the colorimeter because they give inconsistent results.

Recently, Kunkel and Hoagland,¹⁴ besides stating that the barium sulfate suspension has certain disadvantages, have advocated Evans blue dye (T-1824) as a standard of reference. Although this calibration is based on the same general principles of the one here presented, the concentration of 3 γ per cubic centimeter (equivalent to 20 units) appears overestimated, for normal sera give values up to 8 units. It corresponds approximately to 10 units, using the copper sulfate solution as reference.

Ley and associates¹⁵ have described an expression of the values for turbidity as cubic centimeters of barium chloride suspension. Besides being purely arbitrary, and based on barium sulfate obtained from 1 per cent barium chloride, it is subjected to the same criticisms as is Shank and Hoagland's calibration. There is no advantage in eliminating the original expression of results in units.

Additional data are needed to appreciate the value of the thymol flocculation. It has been less often positive, both in hepatocellular and obstructive jaundice, than the thymol turbidity. Apparently thymol flocculation is more useful in the follow-up of chronic hepatitis, as recently demonstrated by Neeffe.¹⁶

SUMMARY

A modification of the thymol test of Maelagan is presented. The values for turbidity are obtained in the Evelyn photoelectric colorimeter, using No. 660 filter and a blank of serum plus physiologic saline. A buffer blank is employed when the thymol solution is more or less turbid.

The instrument is calibrated with a copper sulfate solution and the values expressed in units as originally advocated.

This calibration is easily performed, is independent of the salt brand, and is reproducible.

Flocculation is observed after eighteen to twenty hours and is expressed as 0, 1 plus, 2 plus, or 3 plus.

Normal values with this method are exactly those reported by the originator of the test.

THE COLLOIDAL RED TEST FOR THE STUDY OF HEPATIC DYSFUNCTION

HECTOR DUCCI, M.D.*
SANTIAGO, CHILE

THE colloidal gold test, as modified by MacLagan,¹ is a valuable help in the laboratory study of hepatic disease.¹⁻⁴ Nevertheless, the preparation of the gold sol, used as a reagent in the test, has to be done with meticulous care, following many technical details, which renders it a cumbersome procedure.

Recently, Maizels⁵ has suggested the use of a colloidal suspension of scarlet red which is added to three different dilutions of serum. In this test characteristic changes in color are observed in normal and in pathologic conditions. The main drawback of this reaction is the difficulty that arises in reading the results when icteric, hemolyzed, or opalescent sera are used.

After many trials, we⁶ have adopted a test in which a modified red sol is used and which is carried out following the general principles of MacLagan's colloidal gold reaction. A buffer with a lower pH is used for the colloidal red suspension is more stable than the gold sol.

According to our present experience, the results of this test are the same as those obtained with MacLagan's colloidal gold reaction, and the red test has the advantages of being more reproducible and much simpler.

COLLOIDAL RED TEST

Reagents.—

1. Stock scarlet red solution: A saturated alcoholic solution of scarlet red (Scharlach R, Sudan IV)[†] is made by putting some of the powdered dye in a bottle and dissolving it in absolute ethyl alcohol. It is stored in the incubator at 37° C. at least for twenty-four hours before using. The solution must be saturated.

2. Buffer: (pH 7.53) 0.325 Gm. of barbital-sodium (sodium diethylbarbiturate; $(C_2H_5)_2C:(CONa.CONH):CO$), 0.639 Gm. of barbital (acid diethylbarbituric; $(C_2H_5)_2C:(CONH)_2:CO$) and 0.2 Gm. of phenol (carboic acid; C_6H_5OH) are dissolved in 90 ml. of distilled water with the aid of heat, and after cooling, the volume is taken up to 100 milliliters. The pH is then checked and adjusted if necessary.

3. Scarlet red reagent: 10 ml. of the stock scarlet red solution in a 250 ml. Erlenmeyer flask and 50 ml. of distilled water in a 100 ml. Erlenmeyer flask are warmed to about 55° C. The water is then quickly added to the dye solution. The mixture is boiled first in the water bath and then over gauze till the final volume is about 20 milliliters. The volume is then made up to 800 ml. with distilled water. The reagent is kept in the refrigerator.

Received for publication, June 6, 1947.

*From Section A of Medicine (Dr. Hernan Alessandri), Hospital Salvador.

[†]The "Harleco" dye, prepared by Hartman-Leddon Co., Philadelphia, Pa., has been found suitable for the test.

Procedure.—

In a small Pyrex test tube, 0.05 ml. of serum and 0.5 ml. of buffer are placed. After mixing, 2.5 ml. of scarlet red reagent are added. The results are read, after the tubes have been left undisturbed at room temperature overnight, according to the following:

0 = No change

1 = Faint precipitate, visible only after shaking

4 = Supernatant fluid slightly colored, with heavy precipitate

5 = Clear supernatant fluid with heavy precipitate

(2 and 3 are intermediate grades of flocculation, mainly judged by the color of the supernatant fluid)

The data obtained by using this test, as compared with the cephalin flocculation, the colloidal gold test, the thymol test, the Takata-Ara reaction, and the Gros test, will be the subject of separate communications.⁷

PRODUCTION OF POTENT BLOOD GROUPING SERA

WILLIAM C. BOYD, PH.D.

BOSTON, MASS.

THE procurement of potent blood grouping sera is a problem of importance to all those interested in research in blood groups and during World War II was also a source of concern to the military authorities. It was not until 1944 that Witebsky, Klendshoj, and McNeil¹ published a simple method which seemed to meet the demands. This involved the injection of small amounts of a mixture of A and B substances of animal origin into human volunteers of groups A and B. Since that time a number of workers²⁻⁴ have shown the usefulness of the method.

The present paper is designed to report the results of another routine application of the method of Witebsky and co-workers⁷ and to comment briefly on the safety and suitability of the procedure. From a group of medical students nine volunteers were selected and each given an intravenous injection of 0.9 c.c. of saline mixed with 0.1 c.c. of a solution of mixed A and B substance* (7 mg. of A substance derived from hog stomach, and 5 mg. of A and B substance derived from horse stomach). No women were chosen because of the (very remote) possibility that the injection might at some later date favor sensitization to A or B factors during pregnancy,⁵ but otherwise no selection was exercised, and the first ten men who volunteered were chosen. One of these later became apprehensive and dropped out of the experiment.

In my first use of these A and B materials, fear of an allergic type of reaction following the injection was not entirely absent from my mind at any time.² No such reaction has ever occurred, however, and it is interesting to record that Dr. S. B. Hooker, who before injection tested the present group of volunteers for skin sensitivity to the A and B materials as well as to pork and horse and human salivas of groups A and B, found nearly every individual to exhibit some skin reactivity to one or more of the test substances. One of the subjects exhibited a rather marked reaction to pork. Nevertheless, none of the subjects noticed any reaction, either immediate or delayed, following the injection. The danger from the procedure, judged by the total absence of symptoms in a large number of experiments in addition to those reported here, must be considered negligible.

The increases in isoagglutinin titer are shown in Table I. There was no difficulty, even with such a small group, in selecting from titrations of the trial bleedings one satisfactory A donor and one satisfactory B donor, which was all that was desired. From this and previous work the impression has been gained that about one-half of the volunteers respond with increases of titer and

*Supplied by Eli Lilly and Company, Indianapolis, Ind.

avidity sufficient to make their serum entirely satisfactory for use in routine blood grouping. In the present experiment the titer of the group B sera against A_2 cells was not determined before the injection was made, since it was decided to use one of the donors in any case. The anti- A_2 titer which is shown by Subject 3, however, indicates that there had been a great increase in activity for this subgroup, and earlier work² shows that group B individuals, in fact, often show much greater relative increases in titer to A_2 than to A_1 , as well as great increases in avidity for A_2 . This is one of the notable advantages of the Witebsky method of producing blood grouping sera, for reagents prepared in other ways often show inferior agglutinating power for the A_2 antigen, especially when it is in combination with the antigen B in the subgroup A_2B .¹ Since many of the errors in grouping which are made in hospitals and in the Armed Forces probably result from a failure to recognize the presence of the antigen A_2 , this is a point of considerable importance.

TABLE I. CHANGE IN TITER* OF ISOAGGLUTININS TWO WEEKS AFTER AN INJECTION OF A AND B SUBSTANCE

SUBJECT	GROUP BLOOD	INITIAL TITER		FINAL TITER		
		A_1 CELLS	B CELLS	A_1 CELLS	A_2 CELLS	B CELLS
1	B	128	--	512	128	--
2	B	512	--	8192	512	--
3	B	512	--	2048	1024	--
4	A	--	32	--	--	256
5	A	--	64	--	--	128
6	A	--	64	--	--	256
7	A	--	32	--	--	64
8	A	--	16	--	--	512
9	A	--	8	--	--	16

*Titer equals reciprocal of highest active dilution.

About 300 c.c. of blood were taken from Subject 2 and about 400 c.c. from Subject 8. The amounts of serum recovered from the clotted bloods were about 150 c.c. in each case. These sera seem to keep their activity indefinitely when kept frozen in the deep freeze.

It is interesting to speculate on the possible military applications of Witebsky's methods, in case large amounts of good blood grouping reagents should suddenly be desired in time of war. Suppose we have the problem of grouping 10,000,000 members of the Armed Forces. About twenty tests can be obtained from 1 c.c. of serum, but let us assume that we get only fifteen tests per cubic centimeter. Let us further assume that only one-half of our volunteers respond with the production of satisfactory isoagglutinins and that we obtain an average of 200 ml. of serum per volunteer. (Actual experience indicates that more serum than this can easily be obtained and, furthermore, that the agglutinin titer often remains high enough to enable successive bleedings to be taken at safe intervals. Moreover, many of the sera obtained are so potent that they can be diluted 1:4 or 1:8 with saline before use.) From these very conservative figures we can compute that $2 \times 10,000,000 / (15 \times 200) = 6,666$ volunteers of group A and an equal number of group B will be required. This is a perfectly reasonable number of persons to deal with when one considers the large numbers that can be

vaccinated in a short time, and it is altogether probable that the favorable factors mentioned would reduce the number to little more than 1,000 volunteers of each group, with the result that a single organized center could produce enough blood grouping sera to determine the blood groups of the nation's entire Armed Forces. The expense would be largely confined to costs of personnel to give the injections, determine the final titers,* and package the product. Aside from the packaging and distributing costs, the total expenses might be less than \$1,000.

SUMMARY

A routine use of the Witebsky method of producing potent grouping sera is described, and some considerations as to its suitability and low cost, in peace and in war, are offered.

*Actually, experience indicates that one of the important factors in the inferiority of blood grouping materials prepared in large batches is due to erroneous inclusion in a pool of serum of the serum of one or more individuals who have been erroneously grouped, so it is probable that the best use of technical personnel would be to check the blood groups of each volunteer at least twice. Then the sera of all A volunteers and all B volunteers could be pooled, without doing titers. The sera of the subjects who failed to respond would simply dilute the strength of the final pool, probably by not over a factor of 2, which is easily allowable (see text).

A SIMPLIFIED "QUALITATIVE" METHOD FOR HETEROPHILE ANTIBODY DETERMINATION USING CAPILLARY BLOOD AND A WHITE CELL PIPETTE

ALFRED S. EVANS, M.D.
NEW HAVEN, CONN.

SINCE the demonstration of a heterophile antibody in the serum of patients with infectious mononucleosis in 1932¹ many recognized methods for its determination have been published, all of which depend on the use of inactivated serum. An increasing interest in this disease and the recognition of ambulatory and asymptomatic forms^{2, 3} suggested that a simplified "qualitative" test might be of value in clinic and survey work.

The purpose of this paper is to describe the technique of such a test, using capillary blood and a white cell pipette, and to report the results obtained with its use.

EXPERIMENTAL CONSIDERATIONS AND PROCEDURES

For purposes of comparison with methods using serum for the determination of sheep cell agglutination, dilutions of whole blood must be considered in terms of the amount of heterophile antibody actually present. Since red cells occupy roughly one-half the volume of whole blood in normal individuals, two times any single dilution of whole blood would be the approximate equivalent of any similar dilution of plasma or serum alone in terms of the amount of heterophile antibody. The term equivalent titer will be used in this paper to express this relationship when whole blood dilutions are compared with serum dilutions. This same relationship should be true of most patients with infectious mononucleosis since this disease is rarely associated with an anemia.

Another factor bearing on the use of unheated whole blood for agglutination tests is the presence of hemolysins against sheep cells in normal human serum and in the serum of patients with infectious mononucleosis. Since actual demonstration of this capacity usually depends on the addition of complement as well as on incubation in a water bath, it was believed that less difficulty would be encountered from hemolysis if these procedures were avoided. With these considerations in mind, an experiment with whole blood was carried out to determine the practical applications of these concepts.

Whole Blood Method.—Serial twofold dilutions of citrated whole blood were made in saline solution in amounts of 1.0 ml. each. The tubes were centrifuged; 0.5 ml. of the supernate in each tube was mixed with an equal amount of 1 per cent suspension of sheep red blood cells and centrifuged at 2,000 r.p.m. for one to two minutes. The tubes were then shaken and the highest final dilution to show visible agglutination was taken as the end point; this was doubled to obtain titers comparable to dilutions of serum alone, and they were recorded as such.

From the Section of Preventive Medicine, Yale University School of Medicine.

This report represents work done for the Virus and Rickettsial Disease Commission, Army Epidemiological Board, Office of The Surgeon General, U. S. Army, Washington, D. C.

Received for publication, July 25, 1947.

Standard Method.—The technique of Smith¹ as modified by the Connecticut State Department of Health Laboratories was used. To twofold serial dilutions of inactivated serum in amounts of 0.5 ml. each, an equal volume of 1 per cent sheep red blood cell suspension was added; the tubes were incubated in a 37° C. water bath for two hours, and placed in the icebox overnight. Readings were made the following morning after shaking, and the highest final serum dilution showing visible agglutination was taken as the titer. Agglutination titers of 1:160 or more were considered as definitely elevated and are referred to as "positive" in this paper.

The results of simultaneous determination of sheep red blood cell agglutination titers by the methods outlined are listed in Table I for ten sera, five of which were from patients with proved infectious mononucleosis. It appears that the equivalent titers obtained by both methods were closely comparable. Furthermore, it should be recorded that no hemolysis of sheep red blood cells was observed in the experiments in which unheated whole blood was employed. These observations appeared to substantiate the theoretic considerations discussed previously and formed the experimental basis for the simplified test.

TABLE I. COMPARATIVE RESULTS OF SHEEP RED BLOOD CELL AGGLUTINATION TESTS WITH WHOLE BLOOD AND WITH INACTIVATED SERUM AS MEASURED IN TEN SAMPLES OF BLOOD

SAMPLE	SHEEP-RBC AGGLUTINATION TITER*	
	WHOLE BLOOD METHOD	STANDARD SERUM METHOD
1	20	10
2	20	40
3	10	10
4	40	40
5	80	80
6	160	160
7	640	640
8	640	640
9	640	640
10	1280	1280

*Titer is expressed as reciprocal of serum dilution

THE SIMPLIFIED "QUALITATIVE" METHOD

1. Capillary blood was drawn up to the 0.5 mark in a standard white cell pipette and diluted to the 11 mark with normal saline.
2. This mixture was placed in a small test tube measuring approximately 7 cm. in length and with a diameter of 0.5 cm., and an equal volume of saline was added by refilling the white cell pipette to the 11 mark.
3. The tube was centrifuged at approximately 2,000 r.p.m. for one to two minutes.
4. The supernatant fluid was drawn up to the 11 mark on the white cell pipette and mixed with an equal volume of 1 per cent sheep red blood cell suspension in another small tube.
5. The test tube was centrifuged as before at 2,000 r.p.m. for one to two minutes and then shaken or struck sharply with the tips of the fingers until the sedimented cells became dislodged from the bottom of the tube. If definite evidence of agglutination was seen after thorough shaking, the test was recorded as "positive", if no agglutination was visible and the red blood cells had become resuspended, the test was recorded as "negative."

The term positive is used in the same sense as that just described under Standard Method, that is, a titer of sheep red blood cell agglutination considered unequivocally elevated, while the term negative includes all titers occurring within the normal range. The use of these terms appears justified since the equivalent titer used in the simplified test in these experiments actually corresponds to a dilution of serum of 1:160, previously taken as diagnostic in the standard method. It should be mentioned that a dilution equivalent to 1:80 can be obtained merely by drawing blood up to the 10 mark on the white cell pipette and proceeding as described.

While the designations positive and negative were always used in reporting results, a rough estimate of the actual titer in terms of serum dilution could be gained by observation of the type of agglutination: (1) High titer serum resulted in a tightly packed mass of agglutinated red blood cells that was dislodged easily from the bottom of the tube but tended to remain in large clumps on shaking; (2) titers in the low "positive" range of 1:160 and 1:320 resulted in more finely dispersed agglutinated particles; and (3) titers in the high normal range of 1:80 suggested agglutination when the tube was first agitated, but rapidly went into suspension.

Sheep red blood cell suspensions were often found suitable without rewashing for as long as five days if stored at icebox temperatures.

COMPARISON OF RESULTS OBTAINED WITH THE SIMPLIFIED AND THE STANDARD METHODS

One hundred twenty "qualitative" tests performed on capillary blood by the simplified method were checked by the standard method with serum obtained on the same day, and the results are listed in Table II. It will be seen that in no instance was there disagreement between the results obtained by the two methods: The results of ninety-four tests which were negative by the simplified method using capillary blood, when checked by the standard method using inactivated serum, showed titers that fell into the normal range. Similarly, all twenty-six positive tests using the simplified method were confirmed by finding significantly elevated sheep red blood cell agglutination titers by the standard method. It should also be noted that the results of the simplified test agreed with those of the standard method even at "borderline" titers of 1:80 and 1:160.

Eighty-four additional tests have been carried out by the simplified method. Of these, ten were found to be positive, and subsequent determination by the standard technique on the serum of seven of them confirmed these results. The remainder of the eighty-four tests were negative and were in agreement with the final diagnosis both from a clinical and a hematologic standpoint but were not checked by a standard quantitative method.

TABLE II. COMPARATIVE RESULTS OF SHEEP RED BLOOD CELL AGGLUTINATION TESTS

	STANDARD METHOD										SIMPLIFIED METHOD	
	NEGATIVE*					POSITIVE†					NEGATIVE	POSITIVE
TITER‡	<10	10	20	40	80	160	320	640	1280	2560		
Number of tests	20	29	23	15	7	3	3	11	7	2	94	26
Total tests			94					26			94	26

*Negative = Sheep red blood cell agglutination titer within the normal range.

†Positive = Sheep red blood cell agglutination titer within the range diagnostic of infectious mononucleosis, namely, 100 or more.

‡Titer is expressed as reciprocal of serum dilution

DISCUSSION

The technique of a simplified "qualitative" method of determination of heterophile antibody has been described and the results obtained with this test have been confirmed with a standard quantitative method in 120 instances. The simplified method as used in these experiments was set up at a dilution equivalent to that of a 1:160 dilution of serum. While it has been stated that the presence of agglutination at this titer has been regarded as unequivocal evidence of a significantly elevated titer, it is evident that no precise dividing

point can actually be determined between the normal and the abnormal. It is felt, however, that agglutination at this titer occurs in a negligible number of normal human sera and can usually be accepted as diagnostic of infectious mononucleosis in the absence of recent serum injections. For those desiring a more sensitive test that might indicate early or convalescent cases of infectious mononucleosis, the simplified test is easily adjustable to the equivalent serum dilution of 1:80 as described under Method. Thus at the higher dilution the test can be used as a diagnostic tool and at the lower dilution for survey work during a suspected epidemic.

SUMMARY

1. Theoretic and practical considerations pertaining to the use of whole blood instead of inactivated serum for the determination of sheep red blood cell agglutination have been discussed and investigated.

2. A simplified "qualitative" method of heterophile antibody determination using capillary blood and a white cell pipette has been described.

3. Comparative results of 120 tests determined by the simplified method have been checked using a standard technique and no instance of disagreement found.

4. The simplified test is adaptable either to survey work or to diagnosis.

Appreciation is expressed to Dr. John S. Hathaway, Yale University Health Department, for suggesting the need for such a test as reported and for aid in collecting data, and to Miss Ruth Northey, of that same department, for technical assistance.

A SIMPLE METHOD FOR THE DETERMINATION OF SALICYLATES IN BLOOD

MARIO VOLTERRA, M.D., AND MILDRED D. JACOBS, B.A.
NEW YORK, N. Y.

THE following is a rapid and simple method for determining salicylates in the blood. It is based on the use of the xanthoproteic reaction.

TECHNIQUE

Mix thoroughly 1 ml. plasma or serum with 9 ml. trichloroacetic acid (7 per cent) and let stand fifteen minutes. Filter through a Whatman No. 5 paper (the filtrate must be absolutely clear). Deliver 2.5 ml. of filtrate into a test tube marked at 10 ml. and mix thoroughly with 1 ml. HNO_3 (concentrated). Add distilled water to 5 ml. and mix again. Place in boiling water bath for five minutes. Cool in cold water bath. Add 3 ml. NaOH (60 per cent), mix thoroughly, and cool in cold water bath. Dilute to 10 ml. with water, mix, and read in colorimeter.

RESULTS

The readings by means of the photoelectric colorimeter* with filter No. 511† were plotted against the amounts of sodium salicylates dissolved in normal human plasma‡ (see Table I). Under these experimental conditions the intensity of the yellow color is found to be directly proportional to the concentration;

TABLE I. RECOVERY VALUES OF SODIUM SALICYLATES IN HUMAN PLASMA IN COMPARISON WITH THE THEORETIC READINGS

CONCENTRATION OF SALICYLATE C (MG. %)	COLORIMETER READING R	COLORIMETER READING R	COLORIMETER READING CORRESPONDING TO S C

Received for publication, June 20, 1917.

*Klett-Summerson.

†Corning Glass Works.

‡Human sera contain small amounts of phenol derivatives which contribute to the xanthoproteic reaction. Although they do not correspond to more than 3 mg. per cent (except in cases of renal insufficiency, hepatitis, and a few rare conditions²), this factor was eliminated by preparing the curve with dilutions of salicylates in human serum.

in the present case, by a factor of 8. Thus R, the colorimeter reading, equals $8 \times C$, the concentration of salicylate in milligrams per 100 cubic centimeters.

A series of comparative determinations with our technique and that of Coburn¹ showed them to be in good agreement (see Table II).

TABLE II. COMPARISON OF VALUES BETWEEN XANTHOPROTEIC REACTION AND THE TECHNIQUE OF COBURN¹

NO.	XANTHOPROTEIC	COBURN	DIFFERENCE (MG. %)
1	8.5	9.2	- 0.7
2	37.5	40.0	- 2.5
3	25.5	23.3	+ 2.2
4	15.0	15.0	0
5	7.5	7.9	- 0.4
6	12.0	11.7	+ 0.3
7	15.0	15.0	0

17	38.5	34.0	+ 4.5
18	41.0	40.7	+ 0.3
19	33.0	30.6	+ 2.4
20	18.0	14.2	+ 3.8
21	55.0	49.0	+ 6.0
22	6.0	5.0	+ 1.0
23	30.0	30.8	- 0.8
24	29.0	32.6	- 3.6
25	11.5	10.0	+ 1.5

A series of standard potassium dichromate solutions may be used in place of the photoelectric colorimeter. The shade of the yellow color of diluted potassium dichromate perfectly matches that of the xanthoproteic reaction, as given by salicylate. These potassium dichromate solutions may be used either in the visual colorimeter or in sealed tubes to be matched directly by eye, as in the evaluation of the icterus index. For this purpose 4.08 Gm. of potassium dichromate are diluted to 1 liter to make a stock solution from which the series of standards is prepared. If the stock solution is diluted ten times, the resulting solution is equivalent to 60 mg. of salicylate. Further dilutions may be prepared for values down to 10 mg. per cent.

SUMMARY

A simple and rapid method for the determination of blood salicylates, based on the use of the xanthoproteic reaction, has been described.

THE DETERMINATION OF THE HEART RATE IN THE RAT

SYDNEY M. FRIEDMAN, M.D., PH.D., AND WILLIAM S. MARTIN, B.ENG.
MONTREAL, CANADA

SEVERAL investigators have presented data regarding the heart rate in the rat. Woodbury and Hamilton¹ used the closed optical manometer to compare several species and reported an average rate of 420 per minute. A more usual procedure at present is to calculate the rate from the electrocardiographic tracing.^{2, 3} This latter method has yielded rates averaging 430 per minute.

In view of the fact that these methods require a certain amount of manipulation of the animal, it appeared important to devise a method which would give absolute data for the rat at rest. If this could be achieved, other methods would then be amenable to interpretation. Such a method would be of still greater value in the experimental approach to cardiovascular disease if it recorded not only the rate of the heart, but gave some indication of the force and character of the beat as well. An electric apparatus was devised to meet these requirements.

APPARATUS

The apparatus consists essentially of a crystal pickup arranged to receive impulses directly from the chest wall. The output is fed into a cathode ray oscilloscope. The pattern of the heart sounds appears on the screen and this is synchronized with the sweep of the time base. The time base is calibrated in cycles per minute so that when one complete heart pattern becomes stationary the heart rate corresponds with the repetition rate of the time base and is read directly from the dial.

Pickup.—For unanesthetized animals the stand and holder shown in Fig. 1 are used. The animal is placed in a cardboard holder of correct size in which an aperture large enough to expose the chest surface has been cut. The holder is placed on the carrier slings with the animal's chest directly over the curved brass chest plate. The carrier slings are racked up or down to bring the plate into contact with the chest. Contact should be firm but not constricting. The heart sounds are conveyed through the chest plate and its connecting arm into the crystal. The crystal used is an astatic eartridge type B2.

Oscilloscope.—Fig. 2 presents the wiring diagram for a three-inch cathode ray oscilloscope with its contained amplifier. This apparatus differs from the commercial varieties only in detail. The amplifier unit is designed to provide high gain with good low frequency response down to about 40 cycles per second, which is suitable for the sound frequencies encountered in this work. The time base is adapted for low sweep rates. The frequency dial is calibrated in cycles per minute, and the potentiometer control should have a linear taper to provide a linear scale. The circuit as designed covers the range of 180 to 720 cycles per minute, although switches conveniently extend this range in two further steps. A synchronization control is available to "lock" the heartbeat with the time base. To do this, the frequency rate must be reduced to approximately one-half that of the heart rate. The first heart cycle is used to trigger the time base and consequently does not appear in full on the screen. The following beat, however, appears in full and the pattern remains steady without the operator having to manipulate the frequency control. When this control is used, the frequency reading is meaningless.

From the Department of Anatomy, McGill University.

This work was supported by a grant from the Life Insurance Medical Research Fund.
Received for publication, June 18, 1947.

FIG. 1.

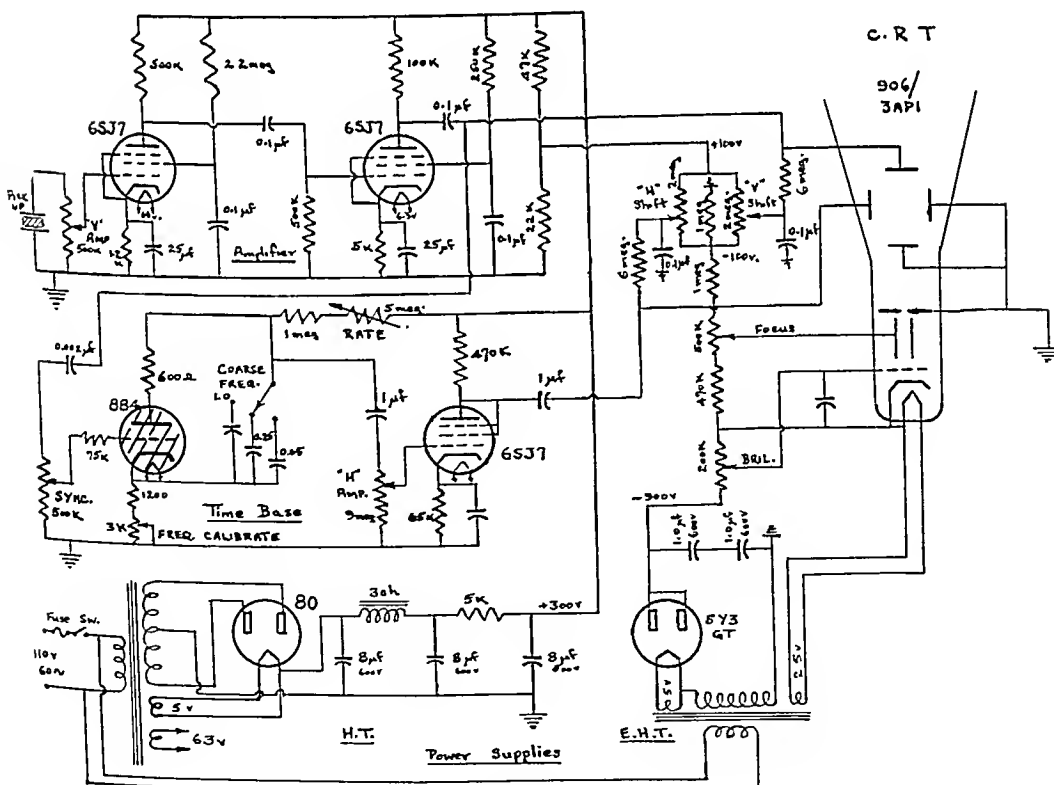

FIG. 2.

EXPERIMENTAL

Data for the heart rate in the unanesthetized rat as well as in animals anesthetized with ether or nembutal are presented in Table I. The normal heart rate of 310 ± 30 in trained unanesthetized animals averaging 150 grams in weight is lower than that previously reported. Nembutal depresses the rate only very slightly, while ether conspicuously increases it.

Fig. 3.

TABLE I

GROUP	NUMBER OF ANIMALS	CARDIAC RATE
Normal trained	22	310 ± 30
Normal untrained	10	480 ± 20
Ether		
Preanesthesia (trained)	5	300
Anesthesia	5	460
20 minutes postanesthesia	5	310
Nembutal		
Preanesthesia (partly trained)	6	350
60 minutes after injection	6	310
90 minutes after injection	6	310
120 minutes after injection (awake)	6	310

Subsequent work made it clear that the heart rate was extremely labile. A short stem chest contact was prepared and the rats held manually. The average rate for such manually held rats was 480 beats per minute. Indeed, in several such animals we were able to observe an increase from a starting rate of about 300 to more than 450 beats per minute in the space of thirty seconds. Similar results were obtained with animals in holders if they had not previously been trained. It was found that steady and reproducible results could be obtained by placing the animals in holders for one-half hour a day and determining the rate on the third day. To simplify this we use standard millboard mailing cartons with screw lids as holders. A hole for the tail is bored through the lid and an aperture for the chest contact cut in one side. Large groups can thus be handled since the actual determination of rate after training is a very brief procedure.

For most purposes nembutal given intraperitoneally in small doses is very satisfactory and avoids the training period without apparently affecting the heart rate appreciably. Fig. 3 shows the heart rate curve in an untrained animal following a light dose of nembutal. Nembutal is also advisable when the heart sounds are to be studied. The normal heart sound picture shows two characteristic low frequency patterns, one of greater amplitude than the other. These sounds are close together and occupy about one-half the duration of the cardiac cycle. Murmurs can readily be seen and interpreted.

SUMMARY

1. An apparatus for the determination of the heart rate in the rat has been described.
2. The normal heart rate in the unanesthetized rat averages 300 per minute.
3. The apparatus also makes possible the study of heart sounds in this species.

EXPERIMENTAL CHEMOTHERAPY OF FILARIASIS

I. EXPERIMENTAL METHODS FOR TESTING DRUGS AGAINST NATURALLY ACQUIRED FILARIAL INFECTIONS IN COTTON RATS AND DOGS

R. I. HEWITT, SC.D., W. S. WALLACE, M.S., E. WHITE, A.B., AND
Y. SUMMAROW, M.D., PH.D.
PEARL RIVER, N. Y.

THE exposure of our armed personnel to filariasis in endemic regions of the Pacific theater of war stimulated the search for new filaricidal drugs in this country. In 1945 a report on the known methods of treatment for filariasis was prepared by Temkin for the Division of Medical Sciences of the National Research Council.¹ In this report are listed the results obtained by various investigators, chiefly with derivatives of heavy metals, in their attempts to cure the disease in man.

Recent reports by Brown² and by Culbertson, Rose, and Oliver-Gonzalez³⁻⁵ demonstrate promising results in man by the use of Lithium Antimony Thiomalate and Neostibosan.

Until very recently the search for new drugs to treat filariasis has been limited because of the lack of a small, easily available laboratory host. A large proportion of the early experimental chemotherapy on this disease was carried out in dogs infected with *Dirofilaria immitis*.⁶ The routine screening of new compounds in the dog, however, is virtually impossible because of the relatively large amounts of drug needed to treat a single animal. Various investigators have reported the successful treatment of *Dirofilaria* infections with antimonials, and Fuadin^{7, 8} is at present the drug of choice for the treatment of heartworm infections in dogs. Otto and Maren⁹ have reported the use of a new arsenical for treating this infection.

Litomosoides carinii, a filarial parasite of the cotton rat (*Sigmodon hispidus*), is now being used in many laboratories for the bio-assay of filaricidal drugs.¹⁰⁻¹³ The vector of this parasite has been found to be the tropical rat mite (*Liponyssus bacoti*)^{14, 15} and several papers have been published regarding the host-parasite relationships.¹⁶⁻¹⁹ Some information has been made available regarding the effects of chemical compounds other than antimonials against this infection,^{10, 11, 23} chiefly the cyanine dyes.

Since April, 1945, filaria-infected cotton rats have been used in these laboratories for the routine screening of various nonmetallie, organic compounds for filaricidal properties. The methods used for bio-assay, both in cotton rats and dogs, and the results of tests on compounds in cotton rats are reported herein.

From the Lederle Laboratories Division, American Cyanamid Co.
Received for publication, Aug. 7, 1947.

EXPERIMENTAL METHODS IN COTTON RATS

Naturally infected cotton rats^o were used as experimental hosts. Animals of various ages and both sexes were used. The number of microfilariae present in the blood stream upon arrival varied considerably, and no method was devised for determining the number of adult worms present in the pleural cavity before treatment was initiated.

Bell and Brown¹⁸ have demonstrated that the microfilariae of *Litomosoides carinii* do not exhibit nocturnal or diurnal periodicity, and our studies confirm these observations (Table II).

Method of Counting Microfilariae.—The first criterion which was used for determining the effect of a new drug against this infection was the behavior of the microfilarial count in the peripheral blood. Rather than strive for absolute, quantitative values it was apparent that much time would be saved by developing a quick qualitative method for examining the blood. Thin smears were made from one drop of blood obtained from the cut tails or toes of the rats. These were air dried and stained with Giemsa's stain, with or without dehemoglobinization. The presence of intact red cells did not materially detract from the ease with which embryos could be found under a low-power objective of the microscope. Generally, from 25 to 100 microscopic fields were counted, but where very few microfilariae were present, 100 fields were always counted. The count from all animals was then expressed per 100 microscopic fields.

It is recognized that this method is subject to considerable error, but our interest was primarily in an all-or-none effect, and all animals under treatment were handled in the same way.

In our first experimental series, microfilarial counts were made on the day before treatment was initiated and every day thereafter for from two to four weeks. In later series this was considered unnecessary, and counts were made only before treatment and on the day of autopsy.

Microfilarial Counts in Untreated Rats.—In Tables I, II, and III data are given from untreated rats for varying periods of observation. In each case it will be noted that considerable fluctuation occurred in microfilarial counts, regardless of how often slides were examined.

The weekly records (Table III) provide the most pertinent information. It will be noted that all of the rats showed a marked increase in microfilariae over a period of several weeks observation. This denotes that the animals were probably infected with worms which had not all reached maturity when received and subsequently discharged increasingly larger numbers of embryos. Similar observations have been made in human infections in children.³ The significance of this observation is that decreases in microfilariae which occur in treated animals are probably greater than actually observed over a period of time.

In only one untreated rat of sixty-five which have been studied has the microfilarial count dropped spontaneously to zero.

Description of Adult Worms in Cotton Rats.—*Litomosoides carinii* is a parasite of the pleural cavity in cotton rats and with few exceptions in more

than 1,000 autopsies adult worms have never been found in any other site. In a few cases no worms were found in the pleural cavity, but several occurred free in the abdominal cavity. When many worms were present they occurred intertwined in masses, generally applied to the dorsal wall, or were located in the pockets formed between the lobes of the lungs and the diaphragm. Frequently, they were applied to the pericardial membrane or to the outer surface of the lungs. Macroscopic host tissue reactions to the presence of living worms rarely were found, and when they were removed the pleural walls appeared shiny, glistening, and apparently undamaged.

Living worms recovered from the pleural cavity invariably undergo writhing movement when placed in 0.8 per cent saline solution and continue this activity for several hours at room temperature. They are sleek, shiny, and transparent when viewed under a binocular dissecting microscope, and the internal structure is clearly defined.

In some animals in which dead worms were found at autopsy, particularly those in which large numbers of worms were killed, extensive adhesions of the heart and lungs to the pleural cavity wall frequently occurred. Isolated dead worms showed no movement whatever when placed in 0.8 per cent saline and were stretched out for their full length. When viewed under a microscope they had a dull, opaque appearance, and the internal structure was not clearly defined.

When dead worms occurred in masses they were sometimes, but not always, encased in a caseous, purulent "exudate." Culbertson and Rose¹² have described a similar substance surrounding dead worms following treatment with antimony derivatives. Bertram, Unsworth, and Gordon¹⁶ have also described this substance surrounding dead worms in white albino rats which were

experimentally infected with *Litomosoides carinii* through the use of the vector *Liponyssus bacoti*. We have found it to consist largely of leucocytes and fat and believe that it represents a response of the host to the presence of decaying worms.

In later stages of decay, dead worms occurred in tight, shrunken masses, were yellowish in color, and were fragmented.

Of sixty-five untreated rats which were subjected to autopsy, nine showed a small number of dead worms. In no case, however, were large numbers of dead worms present, and caseous or purulent material was rarely found.

Methods of Dosage and Evaluation of Drugs in Cotton Rats.—In common with all host-parasite relationships used for evaluating the effectiveness of drugs, several different methods are available to the investigator for determining whether new chemical compounds are active against filariasis in cotton rats. The amount of drug given, route of administration, number of days of treatment, frequency of treatment, and time of autopsy are all variables to which some degree of standardization must be assigned if comparisons are to be made with known filaricidal substances.

Using cotton rats as experimental hosts, the only published reports in detail relative to the effectiveness of treatment with antimony compounds are those of Culbertson and Rose,¹² Culbertson and Price,¹³ and Lawton and co-workers.²⁰ The effect of cyanine dyes against filariasis in cotton rats has been presented recently.^{10, 11, 23} Culbertson and Rose demonstrated that large intramuscular doses of Neostam and Neostihosan (400 to 800 mg. per kilogram) administered once daily, with varying intervals between doses, killed the adult worms and produced a gradual disappearance of microfilariae from the peripheral blood. Essentially the same results were obtained by Culbertson and Price¹³ with Stibanose (Solustihosan). We have been able to confirm these results in a small series of cotton rats.

Due to the paucity of information regarding the effectiveness of compounds other than antimonials against filariasis in any vertebrate host, we believed it important to study effects produced by new compounds against both microfilariae and macrofilariae in our screening tests.

In our program, compounds received for testing were administered orally or intraperitoneally to cotton rats, depending upon their solubility. If a sufficient quantity of the drug was available, 100 to 200 mg. per kilogram were given orally, or 25 to 50 mg. per kilogram intraperitoneally, as a starting dose. Previous experience with drugs used for screening purposes in other host-parasite relationships frequently determined the starting dose. If the animals survived, treatment was administered twice daily for from two to four weeks. For preliminary screening, from one to three animals were used for each test. If the compound proved toxic, and a sufficient supply was available, the dose was halved and retested. Active compounds were tested at many dose ranges.

Insoluble drugs were suspended in a 2.5 per cent solution of corn starch and were administered orally through a 2½ inch, 18-gauge hypodermic needle with a blunted end. Soluble drugs were dissolved in water and were administered intraperitoneally through a ½ inch, 23-gauge hypodermic needle.

In general, autopsies were performed at intervals of from two to four weeks after cessation of treatment, although this procedure was not strictly adhered to in the case of compounds showing suggestive activity in previous tests. Large groups of animals were used when compounds showed an effect against either microfilariae or macrofilariae, and autopsies were performed at various intervals after cessation of treatment. In cases where large masses of living or dead worms were present no attempt was made to count the exact number.

When precipitous and sustained reductions in microfilariae occurred during treatment, or dead adult worms were found at autopsy following treatment, repeated tests were made on compounds producing these effects. Animals with low initial microfilaria counts (namely, less than 10 per 100 fields) were found to be very unsatisfactory for assay purposes, since reductions in microfilariae which might occur were well within the limits of nontreated controls.

Certain obvious sources of error are apparent in the procedures described for the routine screening of compounds against this infection. Longer periods of treatment, more frequent treatment, or longer intervals between cessation of treatment and autopsy might have revealed more active compounds than have as yet been found. Since practically nothing was known about the absorption, excretion, or toxicity of the compounds before tests were made, however, it became necessary to adopt some uniform plan and to treat all compounds alike until experience demonstrated that other methods would produce better results. Similar situations have been experienced in all screening programs, using various host-parasite relationships. Very little is known concerning the mode of action of known filaricidal drugs, and it seemed to us that the trial-and-error method of bio-assay in searching for new drugs was the best method of approach.

EXPERIMENTAL METHODS IN DOGS

Adult *Dirofilaria immitis* commonly occur in the right ventricle of the heart or may be found in the pulmonary artery near the heart. The number of adult worms probably determines the severity of symptoms; namely, emaciation, weakness, jaundice, and a persistent cough. Worms which may be killed by drugs, and probably some which die naturally, are found in the terminal branches of the pulmonary artery within the lung. This has been described by Wright and Underwood⁷ in dogs treated with Fuadin.

If a large number of worms are present in the heart when treatment with an active compound is begun, it has been assumed, and with some good substantiating evidence, that worms which are killed quickly and simultaneously will produce an embolus in the pulmonary artery and kill the dog. Heavily infected dogs, namely, those which show a high microfilarial count with severe symptoms, are therefore considered poor risks for treatment.

In our experiments dogs have been used only for determining the effectiveness of compounds which showed activity in the cotton rat. Essentially the same procedures for treatment were used as described for the cotton rat, and previous results from the rats provided a rough estimate of the probable tolerated dosage in dogs. Oral doses were administered in capsules.

Microfilarial counts from dogs were made by withdrawing 0.05 c.c. of blood from the large vein in one of the forelegs, placing a 22 by 40 mm. cover slip over the blood on a glass slide, and counting the entire fresh preparation. Quantitative methods were more feasible in the dogs than in cotton rats, since fewer animals were used, and measured samples of blood could be withdrawn frequently without seriously disturbing the host.

In some untreated dogs, as well as treated dogs with initial low embryo counts (from 2 to 10 microfilariae per 0.05 c.c.), no adult worms were found at autopsy. This has been experienced by other investigators.

As has been mentioned for cotton rats, dogs with low initial microfilarial counts are unsatisfactory for assay purposes. Any decrease which might occur in the microfilarial count in such animals following treatment cannot be measured either qualitatively or quantitatively. Moreover, a large percentage of these cases invariably reveal no adult worms at autopsy, and the results of treatment are therefore exceedingly questionable.

Following treatment with I'radin, the microfilarial count is reduced within one to several weeks and varying numbers of dead worms are found in the lungs at autopsy.^{7,8} It is frequently necessary to push the dosage to the limit of tolerance, however, and in some cases death occurs from acute toxicity.

For determining the effectiveness of new compounds against *Dirofilaria immitis* infections in dogs, we have used three criteria: (1) a rapid and sustained reduction in microfilariae, (2) presence of dead worms in the terminal blood vessels within the lung at autopsy, and (3) improved physical condition of the animal. The improvement in the physical conditions of animals following treatment is not a certain sign that cure has been effected if it is not accompanied by the destruction of the worms. We have frequently received dogs for treatment which were emaciated, sickly, and unkempt. Some of these animals were caged and fed adequately for a number of weeks preceding treatment, were freed of fleas, and were cured of mange, and all improved in appearance markedly during their pretreatment period, in spite of the fact that a relatively large number of microfilariae were present in the peripheral blood.

COMPOUNDS TESTED FOR FILARICIDAL ACTIVITY IN COTTON RATS

In our screening program, 517 organic, nonmetallic compounds have been tested for activity against *Litomosoides carinii* in the cotton rat. These included 78 organic dyes (phenazines, thiazines, oxazines, triphenylmethanes, phenoxazines, acridines, anthraquinones, and fluorenes); 31 acids and derivatives, 21 aromatic amines, 13 aromatic ketones, 7 amino alcohols, 8 methanes; 16 oxazolidines, 62 guanidines, melamines, biguanides, and guanyls, 112 piperazines, 15 pyridines, 8 metanilamides, 20 sulfonamides, 9 ureas, thionureas, and urethrones, 22 sulfides, sulfones, and sulfonic acids, 16 pyrimidines and pyrazines, 22 piperidines, 4 triazines, 5 quinolines and isoquinolines, 7 cyanamides and diacydiamides, 6 imidazoles and pyrazoles, 8 dioxanes and morpholines, and 25 miscellaneous compounds, including antibiotics and plant extracts.

Several types of compounds showed activity in the cotton rat, either against microfilariae or macrofilariae or both. The best balance between activity and

toxicity, however, was found in the piperazines. The first piperazine tested which showed filaricidal activity was 1-carbethoxy-4-methylpiperazine hydrochloride (180-C). By the oral or intraperitoneal administration of doses ranging from 12.5 to 400 mg. per kilogram, this compound produced a rapid reduction of microfilariae in the peripheral blood and showed suggestive activity against the adult worms. Because of the unique effects produced by this compound and related piperazines, detailed results are presented in separate papers.^{21, 22}

Data concerning active compounds other than piperazines will be presented when more complete information has been obtained.

DISCUSSION

The evaluation of new chemical compounds for therapeutic effectiveness against any naturally acquired infection in animals is subject to considerably more error in the interpretation of results than is the case where standardized infections are produced by introducing known numbers of parasites into laboratory hosts. In the case of such highly standardized infections, for example, as *Plasmodium lophurae* in the duck and *Trypanosoma equiperdum* in mice, a single screening test will often give definite information regarding the effect of a new compound. Moreover, in both of these laboratory infections, several known compounds of widely different chemical structure can be used as control drugs.

For testing new compounds for filaricidal properties, no standardized laboratory infection has as yet been devised. The vectors of both *Litomosoides carinii* in the cotton rat^{14, 15} and *Dirofilaria immitis* in the dog are known, and it is quite probable that in the future a method will be available for testing drugs against experimental infections of known character in these animals. The use of *Dirofilaria immitis* in the dog, however, will probably never prove satisfactory for a large scale screening programs, due to the obvious disadvantages of a large experimental host.

In evaluating the effects of the different types compounds tested in these laboratories, an attempt was made in each case to determine the effect produced upon both microfilariae and macrofilariae in the cotton rat. Sometimes this was not possible, since the animals died while under treatment and the supply of drug was not sufficient to make a second trial. In such cases, when no reduction in microfilariae occurred during treatment and the animals died before the time planned for autopsy, the drug was listed as inactive. Obviously, this cannot be considered a true appraisal of the drug in every case, since compounds are known which produce no direct effect upon the microfilariae but do kill the adult worms.^{12, 13}

The time which elapses between cessation of treatment and autopsy is also a factor which may influence the evaluation of new compounds, as will be demonstrated in subsequent papers.^{21, 22}

Nontreated control animals and animals treated with filaricidal antimony compounds were not included in each protocol in our screening program. The effects of antimony derivatives against *Litomosoides carinii* have been substan-

tially demonstrated^{12, 13} and the course of untreated infections was studied at various times. Since the animals received varied in age, weight, and duration and intensity of infection, and because there was no way for determining how many adult worms were present, any suggestion of activity produced by new compounds was followed by repeated tests.

Recognizing the variables which accompany the use of naturally infected cotton rats for screening new compounds against filariasis, we believe that this host-parasite relationship provides a useful tool in the search for new filaricides, particularly since no other small host is available which will serve the purpose. The correlation between activity in cotton rats, dogs, and human beings infected with filaria has yet to be determined.

SUMMARY

Methods used in testing new chemical compounds for filaricidal activity in naturally infected cotton rats and dogs are described. Data are given relative to untreated infections in cotton rats, and the types of compounds tested are mentioned. The filaricidal effect of 1-carbethoxy-4-methylpiperazine hydrochloride is discussed.

INTRODUCTION

IN THE preceding paper¹ it was mentioned that compound 180-C (1-carbethoxy-4-methylpiperazine hydrochloride) produced a reduction in microfilariae when administered orally or intraperitoneally to filaria-infected cotton rats, and that suggestive action was produced against the adult worms. The effect of this compound, on the microfilariae at least, was so much more rapid than had been reported for any other known compound that an investigation of other derivatives was indicated. The organic chemistry departments of the Lederle Laboratories Division and the Calco Chemical Division of American Cyanamid Company therefore prepared a number of piperazine compounds for testing in the cotton rat. The results of these tests are given in this paper, and the synthetic part of the program is reported elsewhere.^{2, 3}

EXPERIMENTAL METHODS

In addition to the general procedures reported in a previous paper¹ for evaluating the effects of new compounds against filariasis in the cotton rat, supplementary methods were used in the case of the piperazines. Several members of this group of compounds were found to produce precipitous reductions in the microfilarial count following various oral or intraperitoneal doses. For comparative evaluations it was necessary therefore to select what appeared to be the most active derivative and to use this compound as a standard, particularly since no other known filariocidal compounds produced comparable effects. During the first few months of this study, 1-carbethoxy-4-methylpiperazine hydrochloride (compound 180-C) produced the most consistent effect against microfilariae and was used as a standard. Data from eighty-one cotton rats treated with various doses of 180-C are given in Table IV.

Although compound 180-C was markedly effective against microfilariae in well-tolerated doses in the cotton rat, the results obtained against adult worms (Table V), although suggestive, were not promising. Moreover, doses which reduced the microfilariae of *Dirofilaria immitis* in the dog frequently caused nausea, muscular weakness, profuse salivation, and prostration. Another compound was subsequently chosen as a standard. This was 1-diethylcarbamyl-4-methylpiperazine hydrochloride (S4-L). Marked reductions in microfilariae were produced by this compound in doses as low as 3 mg. per kilogram in cotton rats; no serious toxic symptoms occurred in dogs in therapeutic doses; and by frequent administration a large proportion of the adult worms were killed in cotton rats. A detailed report on the effects produced by S4-L in cotton rats and dogs is given in another paper in this series,⁴ but for comparative purposes some data regarding its activity are included herein.

From the Lederle Laboratories Division, American Cyanamid Co., Pearl River, N. Y., and the Calco Chemical Division, American Cyanamid Co., Bound Brook, N. J.

Received for publication, Aug. 7, 1947.

In testing new piperazine derivatives three rats were used for a preliminary assay. If the compound was soluble, intraperitoneal doses of 50, 25, and 12.5 mg. per kilogram were administered twice daily for from two to four weeks. Insoluble derivatives were administered orally in a 2.5 per cent starch suspension at 200, 100, and 50 mg. per kilogram. If preliminary assays proved the compounds to be toxic in the doses used, second or third trials were made, halving the doses each time. Autopsies were performed within one to four weeks after cessation of treatment.

In the case of piperazines which showed activity against microfilariae several dosage regimes were used and an attempt was made to determine an approximate chemotherapeutic index (Table II).

In several cases, due to a difficult synthesis, relatively small amounts of compounds were available. If these showed no activity in doses which were two or three times greater than the minimum effective dose of 84-L, no further tests were performed. It is quite possible, therefore, that some of the compounds listed as inactive in Table I might have shown activity at higher doses.

Types of Piperazines Tested.—In Tables I and II are listed most of the piperazines and related compounds which have been tested thus far in cotton rats. Several other piperazines, some of which were active, will be reported in a later publication. The piperazine nucleus itself showed no activity nor did any of its components. The addition of the carbethoxy radical in position 1, with various substitutions in position 4, produced a number of compounds with high microfilaricidal activity. Alkyl radicals in position 4 retained high activity as far as the propyl and isopropyl derivatives, but butyl substitutions were much less active. Toxicity was increased as the alkyl chain was lengthened.

Retaining the carbethoxy group in position 1, two other substitutions in position 4 retained activity, namely guanyl and carbethoxy.

The only compounds lacking the carbethoxy group which showed marked activity against microfilariae were 1-ethylcarbamyl-4-methylpiperazine hydrochloride (182-L); 1-diisopropylcarbamyl-4-methylpiperazine hydrochloride (177-L); 1-dimethylcarbamyl-4-methylpiperazine hydrochloride (152-L); and 1-Diethylcarbamyl-4-methylpiperazine hydrochloride (84-L). The latter two compounds are considered as the most active of the piperazines yet tested. †

Effect of Piperazines on Microfilariae in the Cotton Rat.—The piperazines listed in Tables II and III produced rapid reductions in microfilariae in the peripheral blood of cotton rats. In some cases the amount of drug necessary to produce this effect was very close to the lethal dose, whereas in others it was far beneath the lethal dose. In general active piperazines in proper doses produced a measurable reduction in microfilariae within twenty-four hours (Table III) after the first dose was administered, and this reduction was sustained for as long as treatment was continued. Recurrences of microfilariae frequently occurred after cessation of treatment.

An exhaustive study of all active piperazines has not been made thus far, since the number of animals and amount of drug necessary to carry out such a study would have been prohibitive, from the standpoint of both time and economy. The comparison given in Tables II and III, however, illustrate the effects of eighteen active piperazines, and Table IV illustrates the effects of different dosage upon microfilariae, using 1-carbethoxy-4-methylpiperazine hydrochloride.

TABLE I. PIPERAZINE AND RELATED COMPOUNDS SHOWING NO FILARICIDAL ACTIVITY IN COTTON RATS IN THE DOSES USED

*Probably not a true value, since the LD₅₀ was determined by intraperitoneal injections and the minimum effective dose by oral administration.

adult worms present in the pleural cavity, and there was no macroscopic or microscopic evidence that any damage whatever to the macrofilariae had been effected. In view of the dramatic effects produced against the microfilariae these results were at first disappointing.

One of the first compounds found to produce suggestive activity against the adult worms was 1-carbethoxy-4-isopropylpiperazine hydrochloride (147-L). Dead worms were found in one of the three rats first used to test this compound, and no adult worms were found in another. The third rat revealed all living worms. Attempts to repeat these results in a larger series of rats failed, because this compound was very toxic to the host and prolonged dosage could not be administered.

Thirty rats treated with various doses of 1-carbethoxy-4-methylpiperazine hydrochloride were then brought to autopsy, and, as illustrated in Table V,

the effects upon the adult worms were extremely variable. Most of the adult worms were alive, however. Similar results were obtained on a smaller series of animals treated with other piperazines effective against microfilariae.

Nine of sixty-five untreated rats which were autopsied showed one or two dead adult worms at autopsy, but in no case were the majority or all of the worms dead. The effects produced by several of the piperazines upon the adult worms in a few rats in each series, therefore, suggested that a wide variety of dosage schedules, with autopsies at different periods after cessation of treatment, might throw some light on the amount of drug and the length of time necessary to kill a larger proportion of the adult worms than had been accomplished in earlier trials. The compound selected for these extensive tests was 1-diethylcarbamyl-4-methylpiperazine hydrochloride, since it produced predictable and rapid reductions in microfilariae in oral or intraperitoneal doses as low as 3 mg. per kilogram, was relatively nontoxic to cotton rats, and was made available in large quantities.

Subsequent data obtained with this compound and reported in a following paper showed that frequent oral dosage for several weeks killed a large proportion of the adult worms. None of the other compounds listed in Tables II and III have been studied so extensively, but it is believed that the best balance between activity and toxicity has been achieved with 1-diethylcarbamyl-4-methylpiperazine hydrochloride. For the reasons described, the activity of the piperazines listed in Tables II and III is based entirely upon their effectiveness against microfilariae. In most cases relatively high toxicity to the host rules out further studies upon their effectiveness against adult worms, and in the few instances where good effects against microfilariae were obtained with relatively nontoxic doses (182-L, 152-L, 180-C) it is felt that further studies would produce little more pertinent information than has been obtained with 84-L.

Effect of Piperazines Upon Dirofilaria Immitis in the Dog.—Several piperazines showing high activity in the cotton rat were tested for effectiveness against

Dirofilaria immitis in the dog. The only two compounds which produced measurable reductions in microfilariae in tolerated doses were 1-carbethoxy-4-methylpiperazine hydrochloride (180-C) and 1-diethylearbamyl-4-methylpiperazine hydrochloride (84-L). The administration of oral or intraperitoneal doses of compound 180-C which produced reductions of microfilariae (25 to 100 mg. per kilogram twice daily) invariably produced nausea, profuse salivation, and muscular weakness. Compound 84-L was much better tolerated, and subsequent experiments in dogs were confined to this derivative. The results obtained with 84-L in dogs, against both micro- and macrofilariae, are presented in another paper in this series.

DISCUSSION

The effectiveness of several piperazine derivatives (administered orally or intraperitoneally) in rapidly reducing the microfilarial count in filaria-infected cotton rats is unique in the experimental chemotherapy of this infection. If the effectiveness of the piperazines was confined to the microfilariae, it would probably indicate that their potential usefulness for treating filarial diseases in other animals and man would be limited. The fact that several of the piperazines tested showed suggestive action against the adult worms, and that one in particular killed a large proportion of the adult worms when administered frequently in tolerated doses for several weeks, certainly removes this group of compounds from the class of experimental curiosities.

The value of the cotton rat bio-assay method for predicting potential filaricidal activity against related diseases in human beings has not been fully tested.

Culbertson, Rose, and Olive-Gonzalez,⁵⁻⁷ however, have demonstrated that a correlation exists between the effects produced by Neostibosan against *Litomosoides carinii* in cotton rats and *Wuchereria bancrofti* infections in man.

We believe it to be important, also, that several of the most active piperazines are effective when administered orally. With the exception of malaria and the intestinal helminth diseases, the chemotherapy of parasitic diseases in man is largely confined to the parenteral administration of various drugs, usually compounds containing antimony or arsenic. The value of some of the heavy metals in the treatment of several of the most important parasitic diseases is not disputed, but the advantages of an effective oral treatment for any disease in human beings or domestic animals are obvious, particularly if no toxic effects are produced.

There is a measurable correlation between structure and microfilaricidal activity in the piperazines, as demonstrated in Table II. We cannot be sure that the most active member of the group has been found, and there is room for further investigation in this respect.

In comparison with several antimony derivatives, the piperazines produce a much more rapid effect upon the microfilariae of cotton rats in the peripheral blood.^{8,9} The effect produced against adult worms by piperazines is very slow in comparison with that of antimony salts. An entirely different mode of action must therefore be involved. No studies have been made thus far in attempts to determine how the piperazines produce their effects upon either microfilariae or macrofilariae.

SUMMARY

The effects of various piperazine derivatives against naturally acquired filaria infections in cotton rats and dogs are discussed. Several compounds in this group produce rapid reductions in microfilariae following oral or intra-peritoneal dosage, and one in particular produces a lethal effect against adult filariae when administered frequently for a period of several weeks.

PEARL RIVER, N. Y., AND BOUND BROOK, N. J.

IT HAS been demonstrated in a preceding paper¹ that the intraperitoneal or oral administration of various piperazine derivatives to cotton rats naturally infected with *Litomosoides carinii* causes a rapid and precipitous reduction of microfilariae in the peripheral blood. Of more than one hundred derivatives made available, 1-diethylcarbamyl-4-methylpiperazine hydrochloride (compound 84-L) was selected as the most promising because of its repeated marked effects against microfilariae in both cotton rats and dogs and because of its relatively low toxicity in these animals. Subsequent studies showed that proper dosage regimes killed a large percentage of the adult worms. The structural formula of this compound is given below.

Two hundred twelve cotton rats and twenty-five dogs have been used to test the effectiveness of this compound against both microfilariae and macrofilariae, and the results obtained are reported herein. The methods used for counting microfilariae and for evaluating the effect upon adult worms have been discussed in a preceding paper.²

Effect of 1-Diethylcarbamyl-4-Methylpiperazine Hydrochloride Against Microfilariae.—After oral or intraperitoneal treatment with this compound in filaria-infected cotton rats, at doses ranging from 3 to 100 mg. per kilogram, the microfilarial count drops precipitously within twenty-four hours (Tables I and II). It then becomes negative or remains at a very low level for as long as treatment is continued.

There may or may not be a recurrence of microfilariae in the peripheral blood upon cessation of treatment (Tables III, V, IX, and X). The extent of

Received for publication, Aug. 7, 1947.

recurrence is related somewhat to the amount and frequency of dosage, although no predictions can be made in this respect. No definite relationship exists between the recurrence of microfilariae and the height of the initial count

(Table V), nor does the height of the initial count affect the rapidity with which the microfilariae disappear (Tables I and II).

The rapidity of the reduction of microfilariae is well illustrated in Table III which gives the results obtained when treatments were administered every two hours. Within two hours after the first oral dose of 25 mg. per kilogram had been administered all animals showed a reduction of over 90 per cent in circulating microfilariae. At the end of twelve hours of treatment (at 5, 10, and 25 mg. per kilogram) many of the rats exhibited no microfilariae in the peripheral blood.

Microfilariae from cotton rats and frogs undergo contortion and spasmodic contractions when placed in solutions of the drug. The microfilariae of *Folyella dolichoptera* from southern frogs³ demonstrate this effect very well when placed in dilutions of 1:100, 1:1,000, and 1:10,000 of 1-diethylcarbamil-4-methylpiperazine hydrochloride. These microfilariae are very large embryos with a narrow whiplike anterior and a thicker posterior end. When placed in contact with solutions of the drug, the anterior end of the embryos contracts immediately into a tight coil, and violent, jerky movements occur. They then straighten out and become completely motionless within five to fifteen minutes. The same effect can be observed upon frog microfilariae in vivo during treatment. Similar effects occur with the microfilariae of *Litomosoides carinii*, although to a lesser extent.

These observations, plus the fact that adult filariae removed from cotton rats in early stages of treatment show no demonstrable damage to the embryos in utero, lead us to believe that this compound acts directly upon the microfilariae in the peripheral blood.

TABLE IV. EFFECT OF 84-L ON THE MICROFILARIAE OF *DIROFILARIA IMMITIS*

DOG	DOSE (MG./KG.)	MICROFILARIAE PER 0.05 C.C. BLOOD									
		DAYS DURING TREATMENT

262	25 Orally, t.i.d.	235	265	-	32	14	4	-	-	-	

In dogs infected with *Dirofilaria immitis*, 1-diethylcarbamil-4-methylpiperazine hydrochloride produces marked reductions in the number of microfilariae during treatment. This effect is most striking in animals with high initial counts (Table IV). The rate of disappearance in dogs is not so rapid as in cotton rats, but within one or two weeks, more than a 90 per cent reduction generally occurs.

Effect of 1-Diethylcarbamil-4-Methylpiperazine Hydrochloride Against Adult Filariae in Cotton Rats.—The effects of treatment with this drug on adult filariae in the cotton rat are not demonstrable so quickly as in the case of the microfilariae. It was apparent from the beginning of this work that demonstrable lethal effects on the adult worms involved a number of variables. The

most important of these have been found to be (1) the amount of drug given, (2) the frequency of dosage, and (3) the number of days elapsing from cessation of treatment to autopsy.

Autopsies performed on untreated rats revealed a small number of dead worms in nine of sixty-five (13.9 per cent). No evidence of massive deaths, adhesions, or large deposits of exudate were found in any of these animals, however, and the number of dead worms formed but a small percentage of the total number present.

TABLE V. COMPARISON OF TREATMENT THREE TIMES DAILY FOR FOURTEEN DAYS AND FOR THIRTY DAYS (S1-L, 25 Mg./Kg.; COTTON RATS)

RAT	MICROFILARIAE PER 100 FIELDS								AUTOPSY RECORD (42ND AND 52ND DAYS)

1094	440	0	0	0	0	4	96	Mass of live worms; one small clump of dead worms	

Of 150 rats treated with 1-diethylcarbamyl-4-methylpiperazine hydrochloride, with doses of 10 mg. per kilogram or more, twice or more daily, 72 per cent showed either some or all adults dead at autopsy or no adult worms.

Table VIII presents in summary form the results of autopsies on 212 rats treated with doses of from 3.13 to 100 mg. kilogram twice or more daily for from two to four weeks. Both oral and intraperitoneal treatments have been included since there is no measurable difference in the effect produced by either of these routes of administration. In general, animals treated with less than 10 mg. per kilogram did not exhibit as many dead worms at autopsy as did those treated with 10 mg. or more per kilogram.

The frequency of dosage also influenced the rapidity with which adult worms were killed. In Table III, for example, dead worms were found on the twelfth day in many rats after dosage was administered every two hours for two days. Dosage three times daily has given more consistent results than dosage twice daily.

Dead worms have been found in animals treated for from two to four weeks, and, as illustrated in Table V, there was no real difference in the condition of the adult worms following these treatment periods. A more striking difference occurred in animals subjected to autopsy at different periods after cessation of treatment. This is illustrated in Table IX and by the comparison of Tables V and X. Of the thirty-eight rats for which data are given in Table X, only three (7.9 per cent) showed all living worms at autopsy. These rats were treated orally three times daily for thirty days with 25 mg. per kilogram, and were then held seventy-seven days before autopsy. All these animals showed relatively high initial microfilarial counts, but in many of them no worms were found at autopsy.

More frequently than not, in animals that showed a rapid and sustained reduction in microfilariae during and after treatment, most of the adult worms were dead or none were found at autopsy. This is illustrated in Tables VI and X. Exceptions did occur, however, as demonstrated in Table VII.

Effect of 1-Diethylcarbamyl-4-Methylpiperazine Hydrochloride Against Adult Filariae in Dogs.—Twenty-five filaria-infected dogs have been treated thus far with this compound or related derivatives. The results are encouraging in that the doses necessary to produce an effect against the microfilariae, and in some cases against the macrofilariae, do not produce signs of severe toxicity. Moreover, oral treatment is effective.

In Table XI, data are given from six dogs treated with intraperitoneal doses. In two of the dogs (Dogs 94 and 108) no adult worms were found in the heart, pulmonary artery, or lung at autopsy. Both of these animals were killed fifty days after the last treatment, and no microfilariae were found in the blood at the time of autopsy. It will be noted, however, that these animals exhibited relatively low initial embryo counts. It has been shown previously² that in many untreated dogs with low initial microfilarial counts the adult worms cannot be found at autopsy in any part of the body. A more certain criterion of cure, therefore, is the presence of dead worms in the terminal branches of the pulmonary artery.

TABLE VI. TREATED ANIMALS IN WHICH DEATH OR ABSENCE OF ADULT WORMS AT AUTOPSY WAS ASSOCIATED WITH CONSISTENTLY LOW EMBRYO COUNTS DURING AND AFTER TREATMENT

In three dogs (Table XI, Dogs 101, 95, and 71) no worms were found in the heart at autopsy, but living worms were recovered from various portions of the pulmonary artery, some in the terminal branches. The remaining dog (Table XI, Dog. 100) was killed relatively soon after cessation of treatment because of a severe case of distemper. Live adults were found in the heart of this animal, but others occurred in the pulmonary artery at various levels.

Data from ten dogs treated orally with 84-L are given in Table XII. In two of these dogs (Dogs 191 and 193) no adult worms were found at autopsy. Marked reductions in microfilariae occurred in all animals with high initial counts, and in three dogs (Dogs 222, 260, and 261) many dead worms were found in the terminal lobes of the lungs. Extensive areas of infarction surrounded the plugged vessels. Upon section,* worms in various stages of disintegration were found.

Dog 225 died after two doses of the drug had been administered. This animal had a very high initial microfilarial count, was severely emaciated, and coughed persistently before and during treatment. Within a short time after the first dose was given it was noted that the animal breathed with difficulty and was in considerable distress. It was found dead in the cage shortly after the second dose had been given. At autopsy a large mass of worms was found in the pulmonary artery near the heart, and these completely plugged the vessel. Since this is the only instance in which this condition occurred we are not convinced that it was due to the administration of the drug. It is quite possible, however, that a simultaneous migration of this large mass of worms from the right ventricle to the pulmonary artery, caused by the presence of the drug in the circulatory system, might have caused the death of the animal.

In addition to the effects produced by the drug on the filariae in dogs, it is of interest that most dogs placed under treatment improved markedly in physical appearance. Most of the dogs when received were emaciated, sickly, and unkempt. Good care and adequate food probably accounted for some of their subsequent improvement, but even in dogs with high initial microfilarial counts, a marked gain in weight and disappearance of symptoms which might be attributed to the presence of *Dirofilaria* took place during and after treatment.

As yet, too few dogs have been used to determine an optimum treatment schedule, but it seems apparent that frequent administration of the drug for several weeks is desirable. Toxicity in dogs with therapeutic doses has thus far been limited to occasional transient nausea.

DISCUSSION

The effect produced against microfilariae in cotton rats and dogs by 1-diethylearbamyl-4-methylpiperazine hydrochloride is certainly more rapid than that reported for any other known compound. Moreover, to our knowledge, this is the first compound shown to produce this effect in experimental animals when administered by the oral route. No data have been obtained thus far with regard to the rate of absorption and excretion of this com-

*Sections prepared and studied by Dr. Frederick Dessau.

pound, but indirect evidence denotes that it is absorbed rapidly when given either orally or parenterally. The better effects produced by frequent dosage indicate that it either is excreted rapidly or is degraded in the body.

Studies are now in progress regarding the fate of the embryos once they are removed from the peripheral circulation.

The failure of this compound to kill all adult worms in all animals treated may be due in part to individual variations in the absorption of the drug. Furthermore, the state of maturity of adult worms, or the number of worms present in the pleural cavity, may influence the effectiveness of treatment. There is no question concerning the more rapid lethal effect of parenteral doses of several antimony derivatives and cyanine dyes⁴⁻⁷ against adult worms in cotton rats. We believe it important, however, that for the first time an organic, non-metallic compound has been found which produces a very marked effect against filariasis in experimental animals when given by mouth.

It should be pointed out that many different dosage regimes have been included in the 212 treated rats for which summary data are given in Table VIII. The best results, as shown in Table X, have been obtained by treating three times daily for thirty days, and then holding the animals for two months before autopsy. In many of the rats treated by this method, no adult worms were found at autopsy, in spite of the fact that high microfilarial counts were present before treatment was initiated. In other rats in this series, varying numbers of dead adult worms were found at autopsy, and in three rats all adult worms were alive. These data, plus the fact that microfilariae sometimes do and sometimes do not recur in the peripheral blood after cessation of treatment demonstrate that a number of unknown variables probably influence the effectiveness of treatment.

The mode of action of this compound against micro- or macrofilariae in the cotton rat is not known. Worms have been found in various stages of decay and disintegration within the pleural cavity after treatment. Worms recovered shortly after death occurred showed no movement when placed in physiologic saline, but no external or internal changes in the appearance of these worms could be noted. Living or dead embryos occurred within the uteri. In other cases, dead worms were found enveloped in caseous, purulent material such as has been described by Culbertson and Rose⁴ following treatment with Neostibosan and Neostam. In very late stages of decay the worms occurred in tight clumps, were usually embedded in a firm, yellowish mass, and were fragmented. In the many cases where no worms were found, the chest cavity was clean and no evidence of fragments of dead worms was found. We have assumed that the dead worm tissue is eventually absorbed.

In some cases where large masses of dead worms were found, extensive adhesions of the heart and lung to the walls of the pleural cavity occurred.

The data obtained thus far from filaria-infected dogs treated with 1-diethylcarbamyl-4-methylpiperazine hydrochloride suggest that this drug may prove useful in the treatment of this infection. As in the case of the cotton rats, individual variations occurred in the susceptibility of the worms to treatment. Emphasis has not been placed upon treated cases in which no adult worms

*Treated several weeks previously with 30 mg. per kilogram of compound 180-C, orally, t.i.d. for forty-seven days. No sharp reduction in microfilariae occurred.

were found at autopsy, since it is well known² that adult worms cannot always be found in untreated dogs which show microfilariae in the blood stream, particularly when the microfilariae are few in number. It is believed important, however, that in three dogs with relatively high initial microfilaria counts large number of dead adult worms were found in the terminal blood vessels of the lung following treatment. These dogs showed marked physical improvement during the course of their treatment; all gained weight and the microfilariae had been reduced rapidly in number. A large series of cases has now been put under observation in order to determine an optimum treatment schedule. It is emphasized again that no disturbing toxic symptoms have occurred during treatment, even though the drug was administered in some cases three times daily for two months. The one death which occurred after two doses had been administered was that of a dog with a very heavy worm burden, and this dog had been in obvious distress several days before treatment was started.

The use of piperazines therapeutically in man is not new, although the use to which they have been put previously has largely been abandoned. Hanzlik³ gives a summary of the literature on the use of piperazine hexahydrate and several similar compounds as urate solvents. Doses as high as 6 Gm. of piperazine hexahydrate have been administered to human subjects without undesirable effects. Other investigators mentioned by Hanzlik, however, report that large doses produce headache, clonic spasms of the extremities, muscular prostration, incoordination, tremor, malaise, and nausea. Piperazine hexahydrate has been reported by several investigators⁴ to be rapidly absorbed and excreted by human patients.

SUMMARY

Data are presented which show the effects produced by 1-diethylcarbamy-4-methylpiperazine hydrochloride on natural infections with filariae in cotton rats and dogs. An immediate and sustained reduction in microfilariae is produced in cotton rats following oral or parenteral administration of the drug. The effect produced against microfilariae in dogs is less rapid but is substantially the same.

Various factors which influence the effects produced on the adult worms in cotton rats are discussed. The maximum number of adult worms are killed when treatment is administered at frequent daily intervals for a period of three weeks or longer, with doses of 10 mg. or more per kilogram.

It is demonstrated that in some *Dirofilaria*-infected dogs treated with the compound the worms were not present in the heart, but were located in terminal branches of the pulmonary artery; and in three dogs, many worms were dead and surrounded by areas of hemorrhage and infarction.

STUDIES IN ERYTHROBLASTOSIS FETALIS

I. ACTIVATION OF THE INCOMPLETE RH ANTIBODY BY THE BLOOD SERUM OF FULL-TERM AND PREMATURE NEWBORN INFANTS

ERNEST WITEBSKY, M.D., MITCHELL I. RUBIN, M.D., AND LIVIA BLUM, M.T.
BUFFALO, N. Y.

THE failure to demonstrate Rh antibodies in the majority of sera obtained from mothers who have given birth to erythroblastotic children constituted, for a while, one of the major difficulties in accepting the theory of isoimmunization advanced by Levine and co-workers as the cause of erythroblastosis. The discovery of a second type of antibody, variously called "incomplete antibody" by Race¹ and "blocking antibody" by Wiener,² removed one of the many remaining puzzling problems connected with erythroblastosis. Investigations of Diamond, Abelson, and Denton,³⁻⁵ as well as of Wiener,⁶ revealed the fact that this new type of antibody agglutinates Rh-positive cells, provided that albumin solution or undiluted serum replaces physiologic saline solution as the diluent.

In spite of quantitative differences, most adult human sera can be used as the diluent for bringing about agglutination of Rh-positive cells by the incomplete antibody. In contrast to this capacity of adult sera, Lubinsky⁷ states that umbilical cord serum cannot be used as a diluent. Wiener,⁸ in discussing the "bizarre behavior of congenital hemolytic disease, so that some infants do not present signs of hemolysis until several hours or days after birth," tried to find an explanation for the sudden appearance of hemolysis after birth in the following mechanism. He suggests the possibility that the so-called X-protein, described by Pedersen,⁹ is involved in the agglutination of Rh-positive cells by the incomplete antibody, and that the late onset of hemolysis is related to the development of this X-protein which does not form until after birth or at the time of birth. Gurevitch, Polishuk, and Hermoni¹⁰ just recently examined umbilical cord serum and the serum of infants up to six months of age and found them devoid of this enhancing property. From this observation they came to the conclusion that there is no evidence for the presumed role of a so-called serum factor or X-protein in the pathogenesis of hemolytic disease of the newborn. Our investigations deal with the characteristics of serum in prenatal and postnatal life with regard to the activation of the incomplete Rh antibody.

From the Department of Bacteriology and Immunology and the Department of Pediatrics, University of Buffalo School of Medicine, and the Buffalo General Hospital and the Children's Hospital.

Received for publication, Sept. 3, 1947.

*The term blocking antibody is considered now to be incorrect. Several other terms have been suggested, such as univalent or glutinin. The need for a generally acceptable term is apparent.

EXPERIMENTAL

Several sera containing Rh antibodies of the incomplete variety, obtained from women with erythroblastotic children, as well as a commercially prepared serum* containing potent antibodies of the same type, were at our disposal. In order to determine the activating capacity of the serum of normal newborn infants, the following experiment was performed:

Decreasing dilutions of serum (volume, 0.1 c.c.) of an Rh-negative patient, Mrs. B., who was delivered of an erythroblastotic child, were mixed with 0.1 c.c. of a 3 per cent suspension of Rh-positive blood cells belonging to Group O. The following diluents for both the serum dilutions and the cell suspensions were used: Column a, physiologic saline solution; Columns b, c, and d, normal adult sera belonging to Groups O, A, and B, respectively; Columns e, f, and g, three normal umbilical cord sera. The mixtures were kept in a water bath for one hour at 37° C. and then spun down at a medium speed for two minutes. The results of this experiment are seen in Table I.

Table I shows that the serum of Mrs. B. failed to agglutinate Rh-positive cells when saline solution was used as a diluent. If, however, normal adult serum was used, Rh-positive cells were agglutinated by Mrs. B.'s serum up to a dilution of 320. Umbilical cord sera, on the other hand, exhibited a remarkably different picture. Serum Wei. almost equalled adult sera in its ability to produce agglutination. In contrast, serum Sil. was considerably weaker in its activating capacity, and serum DeG. fell somewhere in between the two extremes. It should be mentioned that these three normal umbilical cord sera were selected at random.

Differences in the capacity of cord sera to activate the incomplete Rh antibody of various anti-Rh sera become evident from the following experiment as shown in Table II. For this experiment, serum of Mrs. Mar. (Part I), who had given birth to an erythroblastotic child, was compared with a commercial anti-Rh serum (Part II) which we assume was obtained by arti-

*This serum was purchased from Dade County Laboratories, Miami, Fla. Several different batches were used, the first one being of considerably higher potency than the rest.

ficial immunization of Rh-negative volunteers with Rh-positive cells. The experiment was carried out in the following way:

Decreasing amounts of Rh antisera (volume, 0.1 c.c.) were mixed with 0.1 c.c. of a 3 per cent suspension of Rh-positive Group O cells. As diluents for both the Rh serum dilutions and the cell suspensions the following were used: Column a, physiologic saline solution; Columns b, c, and d, normal adult sera selected at random; Columns e, f, and g, normal cord sera selected at random. The mixtures were kept in a water bath for one hour at 37° C. and then spun down at a medium speed for two minutes. The resulting agglutination is seen in Table II.

Mrs. Mar.'s serum (Part I) failed to agglutinate Rh-positive cells when normal cord serum was used as a diluent, whereas adult serum brings out the presence of an incomplete Rh antibody of about average titer.

In Part II of this experiment, incomplete Rh antibodies of rather high titer (commercial Rh test serum) were activated by both adult and cord sera, though even in this case adult serum seemed to be somewhat stronger than cord serum.

The differences in results obtained with these two types of sera probably depend upon the titer of Rh antibodies present in the respective anti-Rh sera. However, the mode of production of the Rh antibody may also be a factor. In one case there was a natural production of antibody in a mother with an

erythroblastotic child, whereas in the other case Rh antibodies were presumably produced by artificial immunization.

The question arose as to whether the serum of premature children, because of its immaturity, would be capable of activating the incomplete antibody. Cord sera of premature babies were thus tested in the following manner:

Decreasing amounts of a commercial Rh test serum (volume, 0.1 c.c.) were mixed with 0.1 c.c. of a 3 per cent suspension of Rh-positive cells belonging to Group O. As diluents for both the Rh serum and the cell suspension the following substances were used: Column a, saline solution; Columns b, c, and d, adult sera selected at random; Column e, cord serum from a 6-month-old fetus who died a few minutes after birth; Columns f and g, cord serum from two premature babies of 8 months' gestation; Columns h and i, cord serum from premature babies born one to two weeks before term; Columns j, k, and l, cord sera from full-term babies. The mixtures were kept for one hour at 37° C., shaken slightly, and then spun down at medium speed for two minutes. The resulting agglutinations are shown in Table III.

The anti-Rh serum under investigation produced a very weak agglutination of Rh-positive cells when diluted in saline. In normal adult serum, however, strong agglutination of Rh-positive cells occurred, notwithstanding the differences between the individual adult sera used for that purpose. The three cord sera obtained from full-term babies also activated the incomplete Rh antibody in this Rh test serum, the strongest cord serum to the same extent as an average adult serum (see Table II, Part II). In contrast, serum of premature babies was characterized by a definite weakness in activating potency, obviously depending upon the age of the babies. Umbilical cord serum from a 6-month-old fetus acted almost like saline solution, while the cord sera of two 8-month-old fetuses were only slightly better than saline solution. The impression gained from this experiment is that cord sera from babies

born one to two weeks prematurely have a somewhat lower capacity for activating the incomplete Rh antibody than the average cord serum of full-term babies. Yet in many instances even the serum of full-term infants seemed to be completely devoid of this activating capacity when tested against maternal Rh antiserum of low or average titer, as seen in Table II. Obviously a maturation factor plays a definite role in the appearance of the characteristics responsible for the activation of the incomplete Rh antibody, as demonstrated by means of a suitable anti-Rh serum containing a potent antibody of the incomplete variety.

In the preceding experiment the maturation principle was shown to be operating during prenatal life. The following experiment was designed to show the continued maturation of this activating capacity in postnatal life. For this purpose an anti-Rh serum whose incomplete antibody was not activated by normal cord serum was used.

Three different serum specimens were collected from each of two babies: (1) cord serum; (2) serum from venous blood obtained twenty-four hours after birth; and (3) serum from venous blood obtained forty-eight hours after birth. Decreasing amounts of serum (volume, 0.1 c.c.) from Mrs. Matt., who had been delivered of an erythroblastotic child, were mixed with 0.1 c.c. of a 3 per cent cell suspension of Rh-positive cells belonging to Group O. Serum and cell suspensions were diluted as follows: Column a, in saline solution; Column b, in adult serum; Columns c, d, and e, in serum specimens 1, 2, and 3 obtained from full-term baby Vi.; Columns f, g, and h, in serum specimens 1, 2, and 3 obtained from full-term baby Ha. The tubes were kept in a water bath for one hour at 37° C. and then spun down at medium speed for two minutes. Table IV shows the results of this test.

TABLE IV. AGGLUTINATION OF RH-POSITIVE CELLS OF GROUP O BY AN ANTI-RH SERUM CONTAINING INCOMPLETE ANTIBODIES ACTIVATED BY ADULT SERUM AND NOT BY CORD SERUM OF NORMAL FULL-TERM BABIES

- , No agglutination; ±, faint agglutination; +, slight agglutination; ++, marked agglutination; +++, strong agglutination.

The incomplete Rh antibody present in the serum of Mrs. Matt. is activated clearly by pooled adult serum. The cord serum of the first full-term baby, Vi., is lacking completely in activating power under the experimental conditions chosen. However, serum specimens obtained from the same baby twenty-four hours as well as forty-eight hours after birth reveal the presence of the activating principle, although it is not equal in strength to that of pooled adult serum.

In contrast, the serum of the second baby, Ha., is still negative forty-eight hours after birth. It should be added that in a different experiment not reported in detail in this paper, a third baby's serum failed to activate the incomplete Rh antibody twenty-four hours after birth, but did so forty-eight hours after birth. It is evident from these experiments, therefore, that in some instances the capacity of a baby's serum to activate the incomplete Rh antibody increases in strength soon after birth and is subject to individual variation.

Considering the fact that the average normal cord serum does not activate the incomplete Rh antibody to the same extent as the average adult serum, the theoretical question is raised as to whether the transfusion of erythroblastotic children with adult's blood may be, at times, contraindicated, due to the fact that the infused adult plasma might activate the incomplete antibody present in the baby. The experimental analysis of this problem presents several difficulties. One of them is that the plasma portion of whole blood taken up in citrate or in a.e.d. solutions is diluted by 75 or 120 c.c. of the crystalloid solution per 500 c.c. of whole blood, resulting in a definite dilution of the blood plasma originally present. In a few experiments it was found that citrated plasma, when compared with serum obtained from the same patient, did not activate the incomplete antibody as well as the serum itself and that the addition of as little as 1 part of saline solution to 2 parts of serum reduced the activating power of the serum remarkably.

Samples of blood obtained from erythroblastotic babies at different periods during exchange transfusions were tested to determine their activating capacities. It was anticipated that with progress of the transfusion the activating capacity of the samples would increase due to the increased percentage of adult plasma in the samples withdrawn. The results of this study in three instances are too irregular to permit the drawing of any final conclusions. Further investigations are needed to elucidate this point.

COMMENTS

On the whole, serum obtained from the umbilical cord of full-term infants, when compared with the average normal adult serum, is characterized by a decreased capacity to activate the incomplete Rh antibody. However, considerable variations do occur. Some adult sera are rather potent in this respect, while others are of relatively low potency. There are a few cord sera which are as strong as adult sera of low or average potency, while other cord sera are weaker than the weakest adult sera tested so far. The susceptibility of the red blood cells used also varies, inasmuch as certain cells are clumped by the incomplete antibody more readily than others. As pointed out by other investigators, agglutination of red blood cells by the incomplete Rh antibody rarely reaches the strength of agglutination frequently observed by the interaction of a strong saline Rh antibody with the corresponding red blood cells.

The serum protein, albumin, and globulin levels were determined on several adult and normal cord sera obtained from full-term babies used in these experiments. In general, the average cord sera contained about 1 Gm. per cent less

of total protein and $\frac{1}{2}$ Gm. per cent less of both albumin and globulin than was found in the average adult serum. However, some of the cord sera which poorly activated the incomplete Rh antibody had serum albumin and globulin levels comparable to those of adult sera which activated the incomplete antibody well. Furthermore, there were no striking differences between protein fractions in the cord sera which did and did not activate the incomplete antibody. Studies of serum protein fractions by more complete methods might give further information.

The experiments reported were carried out by warming the tubes in a water bath at 37° C. This temperature, however, is not essential; room temperature and icebox temperature seem to be equally suitable. The length of incubation necessary to secure maximal agglutination also varies, and while in our experiments the blood-serum mixtures were allowed to stand for one hour, we have the impression that one-half hour is sufficient.

The time and speed of centrifugation are of great importance and determine in many instances the degree of agglutination obtained. The advantage of increased agglutination following prolonged centrifugation at higher speed is frequently outbalanced by the necessity for shaking sediments more intensely at the time of reading, resulting in the breaking up of the clumped cells.

There are certain clinical implications which present themselves as a result of observations reported in this paper. The activating power of serum is apparently dependent upon a maturation factor. Serum of a 6-month-old fetus was practically devoid of activating potency, and the serum of a 7- to 8-month-old fetus showed definitely less activating potency than the cord serum of most full-term babies. The maturation factor becomes apparent and can be easily demonstrated if certain high titered anti-Rh sera, whose incomplete antibody can be activated also by the average normal cord serum, are used. The low titered anti-Rh sera which are not activated even by the normal average cord serum are not useful for the demonstration of the maturation principle during prenatal life. It seems reasonable to entertain the possibility that a certain relationship exists between the capacity of the baby's serum to activate the incomplete antibody and the clinical picture of erythroblastosis. The development of this maturation factor might explain the fact that clinical manifestations become evident only during the second part of pregnancy. In some instances babies are born apparently normal and develop clinical manifestations shortly after birth. This might in some way be related to a rapid increase in activating potency after birth, as was found in several instances.

Because of individual variation, it is not possible to predict the actual status of the activating power of the fetus' serum at any given time. However, the assumption that the factor constantly increases in potency during the last half of pregnancy is justified. Undoubtedly, therefore, the babies are exposed both to the mother's Rh antibody passing from the maternal into their own circulation and to the development of an increased activating capacity of their own blood plasma. The level of activating properties of the serum of erythroblastotic babies examined so far was not appreciably higher than that

of the sera of normal infants of the same age. The school of investigators favoring premature delivery as a therapeutic measure in erythroblastosis fetalis might find additional support for their belief in the observations reported. However, careful clinical judgment should be applied in order to avoid adding the trials of prematurity to erythroblastosis. The induction of premature labor three to four weeks before term in cases where there are reasons to suspect an erythroblastotic baby deserves serious consideration by the obstetrician, who must ultimately make the decision after analysis of the whole problem.

The question of treating erythroblastotic babies with transfusions of adult blood deserves critical thought. Even though it is not possible as yet to prove experimentally an increase of activating potency in the baby's blood plasma following the injection of whole blood, the conclusion that adult plasma given to erythroblastotic babies might possibly increase the danger of intravascular agglutination and hemolysis seems inescapable. An exchange transfusion replacing the larger part of the baby's blood cells would therefore seem to have promise of better results than the simple transfusion of adult whole blood. Furthermore, the transfusion of blood minus plasma (washed red cells) deserves consideration, especially in the milder cases. That even relatively small amounts of adult serum mixed with newborn serum increase the activating power of that newborn's blood serum will be described in a subsequent communication.¹¹

CONCLUSIONS

1. The cord sera of full-term newborn babies are compared with normal adult sera regarding their relative capacities to activate the incomplete Rh antibody and produce agglutination. The results depend upon the type of anti-Rh serum selected for this purpose. Certain anti-Rh sera containing incomplete antibodies of low or even average titer, originating from patients with erythroblastotic children, were activated by normal adult sera, but only slightly, or not at all, by normal cord sera. In contrast, other anti-Rh sera, such as those supposedly produced by immunization of volunteers and containing incomplete Rh antibodies of fairly high titer, were activated by both normal adult serum and normal cord serum. However, even in the latter instance, the average normal cord serum frequently proved to be of somewhat weaker potency than the average normal adult serum.
2. A considerable difference could be demonstrated between the cord serum of babies born prematurely and those born at term when anti-Rh sera containing incomplete Rh antibodies of high titer were used. The cord serum of a 6-month-old fetus seemed to be lacking completely in activating potency, resembling saline solution in this respect. The cord serum of babies born four to eight weeks prematurely exhibited some degree of activating potency though less than the cord serum of full-term babies. The activating power of serum, therefore, depends upon a maturation principle which is subject to considerable individual variation.
3. The maturation of the activating capacity may continue after birth. In order to demonstrate this principle, anti-Rh sera containing incomplete anti-

bodies which fail to produce agglutination with cord serum of full-term babies should be selected. Using anti-Rh serum of this type, differences in the activating power of normal cord serum and normal adult serum become readily apparent. Serum specimens from two of three normal babies taken twenty-four to forty-eight hours following delivery showed an increase in activating power when compared with their respective cord serum, although they had not reached the strength of normal average adult serum. Further studies of the maturation factor in postnatal life are necessary.

4. Considerable individual differences in the activating potency of various sera, cord as well as adult, and differences in the susceptibility of various individual blood cells to agglutination influence the titer of agglutination obtained. The theoretical implications of the reported observations with respect to the development of the clinical manifestations of erythroblastosis and the treatment of the disease by means of transfusions of whole adult blood are discussed.

STUDIES IN ERYTHROBLASTOSIS FETALIS

II. INVESTIGATIONS ON THE DETECTION OF SENSITIZATION OF THE RED BLOOD CELLS OF NEWBORN INFANTS WITH ERYTHROBLASTOSIS FETALIS

ERNEST WITEBSKY, M.D., MITCHELL I. RUBIN, M.D., LILLIAN M. ENGASSER, M.D.,
AND LIVIA BLUM, M.T.
BUFFALO, N. Y.

THE laboratory support of the clinical diagnosis of erythroblastosis fetalis is of ever-increasing importance in order to establish the diagnosis with certainty as early as possible. This need has become more important now that exchange transfusions have been introduced as a method of treatment in severe cases during the first hours of life.

The demonstration of Rh antibodies in the mother's serum is the first indication that she may give birth to an erythroblastotic child, and an increase in this antibody titer during the last half of pregnancy strongly suggests the probability of such an event but does not prove its inevitability. Free circulating Rh antibodies are often found in the umbilical cord serum of erythroblastotic babies. Their demonstration is frequently interpreted as a sign of antibody surplus, indicating that the Rh antigens present in the baby's cells have been completely saturated with the corresponding antibodies. Nevertheless, the presence of these abnormal antibodies in the cord serum is good indication that the baby has been sensitized and might possibly constitute sufficient reason for an immediate exchange transfusion. However, many of the patients with erythroblastosis whom we have had occasion to observe recently showed either no free circulating antibodies or only antibodies of low titer in the cord serum in spite of the fact that these babies exhibited clinical signs of severe blood destruction. In the absence of demonstrable Rh antibodies in the cord serum the laboratory evidence of the baby's sensitization rests upon the demonstration of sensitization of his red blood cells.

Several investigators have described different methods of demonstrating sensitization of the babies' blood cells. Carter and Loughery¹ reported that they succeeded in releasing anti-Rh agglutinins from their attachment to the blood cells of erythroblastotic babies by heating the cell suspensions in a water bath at 56° C. To demonstrate this cell sensitization, Coombs, Mourant, and Race²⁻⁴ use an antihuman globulin rabbit serum which induces the agglutination of erythroblastotic babies' cells but not of normal blood cells. Hill and Haberman⁵ have further demonstrated the usefulness of the Coombs test, and they call it the "developing test." Diamond and Abelson have recommended a test for the

Received for publication, Sept. 3, 1947.

detection of the sensitization of babies' blood cells which they call the "reagglutination test."*

In a preceding paper⁴ observations are recorded demonstrating that sera of premature babies as well as many cord sera of full-term babies were characterized by their relative weakness to activate the incomplete Rh antibody, which was in striking contrast to the capacity of adult serum to activate this antibody. With this in mind the following experiments were designed to determine whether normal adult serum would produce agglutination of red blood cells sensitized with the Rh antibody.

EXPERIMENTAL.

The first four experiments describe typical procedures followed by us for determining sensitization of the blood cells of erythroblastotic babies. A patient, Mrs. Le. (Rh-negative, Group A), with a history of having given birth previously to erythroblastotic children was again delivered of a child exhibiting severe clinical manifestations of this disease. The cord serum of this baby was examined for the presence of free circulating Rh antibodies, the mother's serum taken during delivery being used both for comparison and as a control. The experiment itself was carried out in the following way:

Decreasing amounts of the serum of Mrs. Le. (Columns a and b) as well as cord serum of Baby Le. (Columns c and d) (volume, 0.1 c.c.) were mixed with 0.1 c.c. of a 3 per cent cell suspension of Rh-positive Group O cells. In Columns a and c, physiologic saline solution was used as a diluent for both the serum dilutions and the cell suspensions. In Columns b and d, normal adult serum of Group AB serve as a diluent. The tubes were shaken thoroughly and kept in the water bath at 37° C. for one hour. Then they were centrifuged at medium speed for two minutes. The resulting agglutination is shown in Table I.

*According to a personal communication, this test is carried out as follows: "The baby's cells obtained from cord blood are washed twice with saline. A thick drop of the baby's washed cells is placed on a slide and mixed with a slightly larger drop of whole oxalated blood from a known Rh-positive donor of a compatible blood group. The mixture is rocked for two minutes on a viewing box and at the end of two minutes bound or blocked cells will agglutinate the Rh-positive blood of the donor."

The Rh antibody titer of Mrs. Le.'s serum was 128, irrespective of whether saline solution or normal adult serum was used as a diluent. In contrast, no Rh antibodies were demonstrable in the cord serum under the experimental conditions employed. In view of the baby's severe clinical manifestations of erythroblastosis, however, it had to be assumed that the baby's red blood cells were sensitized.

Suspensions of red blood cells in this and in subsequent experiments were prepared from cord blood by the following method:

Umbilical cord blood was allowed to stand until clotted. The clot was then loosened from the sides of the test tube and centrifuged in order to precipitate the clot of cells and separate the serum. After the larger part of the supernatant serum had been decanted, the blood clot was broken up with wooden applicators and the cells resuspended in the small remaining portion of supernatant serum. In other instances, the blood clot was squeezed through several layers of gauze in order to obtain a suitable cell suspension. If the suspensions of blood cells were not homogenous, they were filtered through a paper filter of a type that allowed the passage of red blood cells. (The paper filter was first moistened with cord serum, if available; if not, with saline solution.) Finally, the cell suspension was spun down thoroughly, the supernatant being removed as completely as possible by means of a dropping pipette. The cell sediment was not submitted to any washing procedures.

In order to demonstrate the sensitization of the blood cells under investigation, the following experiment was carried out:

Packed Baby Le.'s cells, 0.0125 c.e., were mixed in test tubes with 0.3 c.e. of: (1) three different normal adult sera (Columns a, b, and c), (2) two normal cord sera (Columns d and e), and (3) cord serum of Baby Le. (Column f). The mixtures were shaken thoroughly and kept for one hour in a water bath at 37° C. They then were shaken slightly and spun down by centrifugation for two minutes at medium speed. The results of this experiment are seen in Table II.

TABLE II. TEST TUBE AGGLUTINATION OF BABY LE'S CELLS SUSPENDED IN VARIOUS ADULT SERA AND IN CORD SERA, RESPECTIVELY

-, No agglutination. ±, faint agglutination. +, slight agglutination. +++, strong agglutination.

When Baby Le's cells were suspended in three normal adult sera in test tubes, varying degrees of agglutination occurred. However, when cord serum, including that of Baby Le., was used as a diluent, there was no agglutination. Obviously, therefore, Baby Le's cells were sensitized, but visible agglutination did not occur unless the baby's cells were suspended in adult sera which are suitable for activating the agglutination of Rh-positive cells sensitized by the

incomplete Rh antibody. The specificity of the agglutination observed becomes evident from the following experiment:

Packed cells, 0.01 c.e., obtained from three different sources (Column a, blood cells of Baby Le.; Column b, normal adult blood cells, Group O, Rh-positive; and Column C, normal adult blood cells, Group A, Rh-positive) were mixed, in the first row, with 0.3 c.e. of normal serum Group A and, in the second row, with 0.3 c.e. of Group A citrated plasma originating from the same individual from whom the normal Group A serum was obtained. The experiment was carried out in two parts, Part I being kept in the water bath for one hour at 37° C. and Part II in the icebox for one hour at 4° C. The tubes were then spun down in the centrifuge at medium speed for two minutes. The resulting agglutinations are shown in Table III.

TABLE III. TEST TUBE AGGLUTINATION OF BABY LE.'S CELLS BY NORMAL ADULT SERUM AND PLASMA, RESPECTIVELY

Plasma Group A 0.3 c.e.	++	-	-	±	-	-

- , No agglutination; ±, faint agglutination; ++, marked agglutination; +++, strong agglutination.

The specificity of the agglutination of Baby Le.'s cells suspended either in normal adult serum or in normal adult citrated plasma becomes apparent. Two cell suspensions from normal individuals similarly prepared failed to show any agglutinations. In this experiment agglutination of the baby's cells appears to be stronger at body temperature than at icebox temperature.

The agglutination of Baby Le.'s cells in normal adult serum could also be shown very clearly on the slide. As a matter of fact, the slide technique which was carried out in the following manner proved to be most valuable for demonstrating sensitization of this baby's cells.

With a wax pencil, two rings about 2 cm. in diameter were made on a clean microscope slide. In the center of one ring two large loopfuls (or their equivalent) of packed washed Baby Le.'s cells were placed. In the second ring the same amount of packed normal adult Rh-positive cells of Group O was placed. One large drop of normal adult serum of Group A* was added to each ring and the mixtures were stirred with wooden applicators. The slide was constantly tilted back and forth by hand, or was placed on a viewing box as recommended by Diamond, and rocked for a few minutes. Frequently five to ten minutes elapsed before agglutination occurred.

An alternative method to the one described consisted of the following: One large drop of adult serum of Group A was placed in each of two rings on a slide. Two wooden applicators were placed in the test tube containing packed

*Since Baby Le. belonged to Group A, serum of Group A or of Group AB was used in all experiments.

Baby Le.'s cells. The sticks were removed and placed into the first drop of serum on the slide. Sometimes this was repeated, using the other ends of the sticks, in order to insure at least a 10 to 20 per cent cell suspension. Normal Rh-positive Group O cells were added to the second drop of serum in the same manner.

The agglutination of the baby's cells never reached the stage of one solid clump. Instead, agglutination was observed at first only with a magnifying glass, and finally, as time elapsed, ended with the production of many clumps of larger size. Oxalated adult plasma also proved very suitable for demonstrating sensitization. Agglutination of Baby Le.'s cells when taken up in a drop of oxalated plasma on a slide occurred faster and appeared to be even stronger than when taken up in a drop of serum. However, normal cells, too, agglutinated occasionally in oxalated plasma. The addition of one drop of normal saline solution to these latter preparations resulted in a dispersion of the agglutination of the normal cells but did not disturb the agglutination of Baby Le.'s cells. Nevertheless, because of its possible nonspecific effect we feel that oxalated plasma should not be used routinely for this purpose and that serum is the diluent of choice.

Since the cord serum of Baby Le. did not produce agglutination of his own sensitized cells, the following experiment was conducted to determine whether mixtures of Baby Le.'s serum and normal adult serum would induce agglutination of Baby Le.'s cells in view of the fact that this would have important clinical implications. Several mixtures of Baby Le.'s cells with various dilutions of normal adult serum in his own serum were prepared:

- 1 part of normal adult serum of Group A plus 29 parts of cord serum (Baby Le.).
- 1 part of normal adult serum of Group A plus 9 parts of cord serum (Baby Le.).
- 3 parts of normal adult serum of Group A plus 7 parts of cord serum (Baby Le.).
- 1 part of normal adult serum of Group A plus 1 part of cord serum (Baby Le.).
- 3 parts of normal adult serum of Group A plus 1 part of cord serum (Baby Le.).

Two rings about 2 cm. in diameter were drawn on each of four microscope slides with a wax pencil. One large drop of each of the described five mixtures was placed in five separate rings. One drop of undiluted cord serum (Baby Le.) was placed in the sixth ring and one drop of the same normal adult serum undiluted in the seventh ring. The eighth ring contained one drop of 20 per cent albumin solution. To each of these drops, Baby Le.'s packed cells were added by means of wooden applicators as described previously. The mixtures were stirred and constantly rocked on a viewing box and read after ten minutes. Table IV shows the results of this experiment.

TABLE IV. SLIDE AGGLUTINATION OF BABY LE.'S CELLS BY VARIOUS MIXTURES OF CORD SERUM AND NORMAL ADULT SERUM

-	+	++	+++	++++	-	++++	-

- , No agglutination; + , slight agglutination; ++ , marked agglutination; + + + , strong agglutination; + + + + , very strong agglutination.

Undiluted normal adult serum produced strong agglutination of Baby Le.'s cells, whereas Baby Le.'s own cord serum failed to do so at all. The addition of increasing amounts of adult serum to the cord serum results in mixtures which have an increasing capacity to agglutinate the sensitized cells. It is interesting to note that a mixture consisting of as little as one part of normal adult serum and nine parts of cord serum agglutinated Baby Le.'s cells even though the degree of agglutination was rather weak. Baby Le.'s cells were not agglutinated in 20 per cent albumin solution under these experimental conditions, an observation which we made repeatedly. Obviously, albumin solution was not a suitable medium for bringing out the agglutination of Baby Le.'s sensitized cells in the slide test.

The experimental results obtained with the serum and cells of Baby Le. may be considered to be typical of erythroblastotic babies whose cord sera do not contain any demonstrable free antibodies. The following three experiments deal with a case in which free Rh antibodies were found in the cord serum.

Mrs. Bar. (Group A, Rh negative), whose serum during pregnancy showed a rather high titer of Rh antibodies of the incomplete variety, was delivered at term of a baby exhibiting severe clinical manifestations of erythroblastosis. The baby belonged to Group A and was Rh positive. An exchange transfusion was successfully performed using Rh-negative, Group A blood. A sample of blood was obtained after each infusion of about 60 c.c. of the donor's blood. Nine blood specimens were collected in Wassermann tubes at regular intervals during the exchange transfusion, the first one being taken before the transfusion started, the last one at the end of the transfusion. The first four blood specimens failed to clot, whereas the remaining ones did, possibly due to the heparin used. The baby's serum (or plasma) collected at the beginning of the transfusion was examined for Rh antibodies in the manner described in the first experiment (Table I). An Rh antibody of the incomplete variety was found in a titer of 16. No saline Rh agglutinin was present. (The mother's incomplete Rh antibody titer was quite high at the time of delivery, above 250.)

In the experiments to be described, the nine blood specimens obtained from Baby Bar. during the exchange transfusion were spun down and the supernatant sera were removed from the sediments. Inasmuch as the sediments of Sera 5 through 9 consisted of blood clots, cell suspensions were prepared as described in the case of Baby Le. The cell sediments of Sera 1 through 4 were not treated further and were used as such. None of the cell suspensions was washed.

In order to determine if Baby Bar.'s red blood cells were sensitized by Rh antibodies the following experiment was carried out: With a wax pencil, ten rings were drawn on five slides. In the first nine rings one drop each of the nine serum specimens obtained during the exchange transfusion was placed. One drop of normal adult serum of Group A was put into the tenth ring. Baby Bar.'s cells obtained from the first blood specimen, drawn before the blood transfusion was begun, were then added to each drop of serum by means of wooden applicators. The concentration of blood cells finally obtained

was estimated to be about 20 per cent. The mixtures within each ring were stirred thoroughly and then placed upon the viewing box and constantly rocked. After ten minutes the results were noted and are recorded in Table V.

- , No agglutination; +, slight agglutination; ++, marked agglutination; +++, strong agglutination.

The serum of Baby Bar. (Serum 1), when added to its own cells, produced agglutination on the slide. Surprisingly enough, however, Sera 2 to 8, taken during the exchange transfusion, failed to do so. The last serum, 9, again gave a weak agglutination. Normal adult serum of Group A, when mixed with Baby Bar.'s cells, resulted in a strong agglutination. At the present time we are unable to explain why the serum specimens obtained during the exchange transfusion failed to produce any visible agglutination of Baby Bar.'s cells.

It is the obvious goal of an exchange transfusion to replace the baby's blood with normal blood free of Rh antibodies. For that purpose Rh-negative blood is used by most investigators. During the procedure the donor's Rh-negative blood cells are constantly mixed in ever-increasing amounts with the baby's Rh-positive blood cells. The presence or absence of Rh-positive blood cells in the blood specimens taken during exchange transfusions may be considered a rough indicator of the success and extent of the operation. To this end the following experiment was carried out on the series of blood specimens obtained from Baby Bar. during the exchange transfusion.

From the blood sediments of the nine specimens obtained from Baby Bar. during the exchange transfusion 2 per cent blood cell suspensions were prepared in physiologic saline solution. As controls, 2 per cent suspensions of normal Rh-negative and of normal Rh-positive cells were used. In the first row of tubes (Column a) 0.05 c.e. of each of the 2 per cent cell suspensions was mixed with 0.05 c.e. of anti-Rh test serum 1 (anti-D, 85 per cent); in the second row (Column b), with anti-Rh test serum 2 (anti-D, 85 per cent), and in the third row (Column c), with 0.05 c.e. of physiologic saline solution. After being shaken thoroughly, the tubes were kept for one hour at room temperature and then centrifuged at medium speed for two minutes. The resulting macroscopic agglutination is shown in Table VI.

The two Rh test sera secured from different sources strongly agglutinated the Rh-positive cells which were used as controls. The first test serum agglutinated Baby Bar.'s cells taken from the first and second specimens, while cells

from the third specimen were negative with this serum. In contrast, the second anti-Rh test serum strongly agglutinated Baby Bar.'s cells up to and including the sixth specimen; blood cells from the seventh specimen failed to show agglutination. Obviously the strength and quality of the Rh test serum used are of great importance in the detection of the baby's Rh-positive cells in blood mixtures resulting from exchange transfusions. The agglutination of the baby's Rh-positive cells by anti-Rh serum seems to be a practical way of testing for their presence in mixtures consisting of both the baby's blood cells and the donor's blood cells as obtained during exchange transfusion. However, the interpretation of this latter observation is not entirely clear. First, the agglutination of the baby's sensitized cells may not have depended solely on the presence of antibodies in the anti-Rh test serum. It has already been pointed out that normal adult serum will induce agglutination of sensitized red blood cells. Second, Baby Bar.'s umbilical cord serum contained a free circulating antibody, suggesting complete sensitization of Baby Bar.'s Rh-positive cells. The question thus arose as to why Baby Bar.'s cells were still subject to agglutination by anti-Rh sera. In order to elucidate these two points, the following experiment was performed.

Twenty circles (about 2 cm. in diameter) were drawn with a wax pencil on several slides. One drop of commercial anti-Rh serum (recommended for the slide technique) was placed in each of ten rings, one drop of normal pooled adult serum of Group A being placed in a second group of ten rings. To the first nine rings of each group packed cells of Baby Bar. prepared from the nine different specimens obtained during the exchange transfusion were added by means of wooden applicators. The tenth ring of each series was used as a control for which normal Rh-positive cells of Group A were used. The slides were placed on the viewing box, rocked, and the resulting agglutination observed after about ten minutes. Table VII shows the findings of this experiment.

The commercial anti-Rh serum agglutinated Baby Bar.'s cells up to the fifth specimen, while cells taken from the sixth specimen failed to show any

agglutination. However, normal adult serum also allowed the recognition of the baby's sensitized cells up to the fifth specimen, thus resembling very closely the results obtained with the anti-Rh serum. The fact that the serum containing anti-Rh antibodies was no more effective in agglutinating this particular baby's cells than was the serum without antibodies would lead one to conclude that in addition to Rh antibodies the serum itself is an important factor. Until further evidence is obtained we do not recommend that this test be used as a guide as to the amount of blood that should be given in an exchange transfusion.

DISCUSSION

The findings reported in this paper have been essentially confirmed by the last six cases of erythroblastosis which we have studied. All six infants exhibited severe clinical manifestations of the disease. Two died shortly after birth before treatment could be administered, while the other four were treated by means of exchange transfusions and lived.* In all six cases the mothers were Rh negative and the babies were Rh positive. Further studies are necessary to determine the sensitivity of the described methods and the applicability of this technique to the detection of mild forms of erythroblastosis.

Normal adult serum, active as well as inactive, was found to be the most suitable diluent for bringing about the agglutination of sensitized cells obtained from babies with erythroblastosis fetalis, especially when the slide test was used. Why albumin solutions, 20 per cent as well as 30 per cent, were not suitable for this purpose is not quite clear. However, these latter solutions can be used successfully in the test tube. Oxalated plasma also proved to be a good medium, its only disadvantage being that it frequently produced a non-specific type of pseudoagglutination. Nonspecific reactions with the use of normal adult serum have not been observed while examining the cases under consideration. However, in the study of a larger series of normal cord bloods, pseudoagglutination (rouleaux formation) was occasionally encountered, thus making it necessary to observe the slides microscopically. Therefore, from a diagnostic standpoint, the agglutination obtained must be interpreted with great

*We are very much indebted to Dr. Douglas P. Arnold who performed the four exchange transfusions and furnished us with the material for these studies.

care. The presence of even small amounts of saline solution prevented or reduced the agglutination of the baby's sensitized cells. For this reason, packed unwashed cells were used with undiluted adult serum. Wiener⁷ reported the agglutination of red blood cells of erythroblastotic babies when these cells were suspended in their own cord sera. In our experience, cord sera are considerably inferior to normal adult sera in this capacity. One case exhibiting a somewhat different feature from the cases described herein seems to be worthy of mention in this connection. In this instance the preparation of a cell suspension from the baby's cord blood clot was more difficult than usual because of a marked degree of hemolysis. The cells were found to be Rh positive and were considered to belong to Group A₂B. The B property of the baby's cells was strongly and definitely agglutinated by an anti-B isoagglutinin; the presence of the A property, however, was somewhat questionable in spite of the fact that both test sera, produced by immunizing donors with blood group-specific substances, were very potent.⁸ When normal serum of Group AB was added to the baby's blood cells, the same weak type of agglutination occurred as was obtained with test serum of Group B, indicating that the agglutination of these cells was not due to the interaction between an A antibody and an A factor, but to the fact that the baby's cells were sensitized with an Rh antibody, thus exhibiting agglutination when suspended in normal adult serum. This child's mother belonged to Group O, and one could have construed very easily an exemption to the Bernstein law of inheritance of the blood groups.* The baby's cells, even when suspended in saline solution and examined under the microscope, already showed in each field occasional clumps consisting of five to ten cells. When the baby's packed cells were added to normal cord serum on a slide, macroscopically visible agglutination occurred. The baby's own cord serum was not available.

As a result of the difficulty experienced in the determination of this baby's blood group, one wonders if similar difficulties might be encountered in the determination of the Rh type of erythroblastotic babies. In many instances the baby's Rh type is considered to be positive because agglutination of the cells occurs following the addition of an anti-Rh serum. The question arises as to whether agglutination of red blood cells from erythroblastotic babies by an anti-Rh serum is actually caused by the Rh antibody proper, or whether it is merely due to the addition of normal adult serum. Surprisingly enough, agglutination takes place even in instances in which the baby's cord serum contains free circulating Rh antibodies which, one might assume, had combined with all the available Rh antigens present in the baby's cells. The interpretation of agglutination tests with the blood cells of erythroblastotic babies, therefore, needs careful observation from the standpoint of specificity.

Adult serum of any group can be used to bring about agglutination of the baby's sensitized cells by the slide technique, provided that the blood group

*In order to avoid this statement being misused legally to question the validity of Bernstein's rule, it should be added that this baby, if it had survived, would soon have replaced its sensitized cells with normal cells and would have shown its true blood group a few weeks after delivery.

corresponds to that of the cells. Since there are considerable individual variations in the suitability of individual adult sera, pools can be prepared from adult sera of the same blood group. If the baby belongs to Group O, no attention need be paid to the blood group of the adult serum to be used. In cases where the baby's blood group is unknown or is questionable, serum of Group AB is the safest one to employ.

From the standpoint of treatment, the observations reported in Table IV may be significant. This experiment showed that the addition of as little as 1 part of adult serum to 9 parts of the baby's cord serum induced macroscopically visible agglutination of the baby's cells on the slide. Thus the transfusion of 30 to 50 c.c. of adult whole blood into a newborn baby might be sufficient to enhance the in vivo agglutination of the baby's sensitized cells, resulting in further damage to them. Experimental evidence supporting this theoretical possibility, however, has not yet been found. What happens to the activating properties of adult plasma following transfusion into an erythroblastotic baby still remains unknown.

CONCLUSION

A simple technique for the demonstration of sensitization of the red blood cells in an erythroblastotic baby is described. Agglutination occurs when the packed blood cells of an erythroblastotic baby are suspended in normal adult serum. This test can be carried out either in test tubes or on microscopie slides, the use of the latter proving more sensitive in our hands. The results obtained from this test indicate that the baby's cells are sensitized by the incomplete type of Rh antibody which does not cause agglutination in saline solution, and only slight agglutination if any, in cord serum. Blood specimens taken from erythroblastotic babies during exchange transfusions were examined for the continued presence of sensitized cells. Some practical aspects concerning the validity and specificity of Rh type and blood group determinations of erythroblastotic babies, as well as the treatment of these babies by blood transfusion, are discussed.

THE URINARY EXCRETION OF PTEROYLGLUTAMIC ACID AND CERTAIN RELATED COMPOUNDS

T. H. JUKES, PH.D., A. L. FRANKLIN, PH.D., E. L. R. STOKSTAD, PH.D.,
AND J. W. BOEHNE, III, B.S.
PEARL RIVER, N. Y.

IT BECAME evident in the early stages of the investigations of *Lactobacillus casei* factor (folie acid) that only small amounts were excreted in the urine of normal human subjects.^{1, 2} The amount excreted daily was estimated to be less than 1 per cent of the probable dietary intake.²

These observations indicated that dietary pteroylglutamic acid was probably broken down before excretion. Later, pure pteroylglutamic acid (PGA) became available for administration as a supplement. It then appeared that the amount of pteroylglutamic acid excreted in the urine increased sharply as the dosage was raised, indicating that the capacity of the body to break down pteroylglutamic acid was limited. A corollary of these observations was that pterioic acid did not appear to be excreted as a breakdown product of dietary pteroylglutamic acid because, on a normal unsupplemented diet, the potency of the urine was low when measured either by *Streptococcus faecalis* R¹ or *L. casei*.²

In a study carried out with young men on a normal diet, it was found that the average daily urinary folie acid excretion was about 4 μ g as measured by assay with *Str. faecalis* R.³ Supplementation with a very small amount (90 μ g) of pteroylglutamic acid daily did not increase the urinary excretion.⁴

The daily urinary excretion of pteroylglutamic acid was found to be 2 to 4 μ g, rarely exceeding 5 μ g, on ordinary diets.⁵ Oral or parenteral administration of pteroylglutamic acid led within twenty-four hours to an excretion of 15 to 75 per cent of the amount administered, depending on the size of the dose; one individual excreted 16 per cent of an intramuscular dose of 1 mg., while with a dosage of about 10 mg. daily, either orally or parenterally, the excretion usually ranged between 35 and 50 per cent. When pteroyltriglutamic acid was administered to a patient with sprue, assay of the urine with *L. casei* and *Str. faecalis* R indicated that pteroylglutamic acid was liberated from pteroyltriglutamic acid and excreted in considerable quantities.

Doses of 5 to 16 mg. of pteroylglutamic acid were fed to nine normal subjects and nine hospital patients.⁶ The normal subjects before receiving pteroylglutamic acid had an average daily urinary excretion of between 2 and 3 μ g of pteroylglutamic acid. They excreted an average of 28.5 per cent of the administered dose. Most of the excretion took place between the second and eighth hour after dosage. The hospital patients excreted much lower percentages of the administered dose.

Studies with six normal subjects⁷ showed that only about 3 μ g of pteroylglutamic acid, as measured by assay with *L. casei*, were present in the twenty-

four hour urine prior to administration of pteroylglutamic acid. When 4 mg. of the compound were given, about 32 per cent of the dose was excreted in the urine in twenty-four hours.

EXPERIMENTAL.

Normal adult men were used as subjects. Since it was found that on ordinary diets the pteroylglutamic acid (PGA) content of the urine was very low (between 5 and 10 millimicrograms per milliliter) no attempt was made to control the diet and, except when very small test doses were used, it was unnecessary to apply a correction for the basal value of the urine.

Samples were collected in brown bottles and preserved under toluene in the refrigerator. Folic acid was assayed against a pteroylglutamic acid standard with *Str. faecalis* R,^s using purine, pyrimidine, amino acid, and vitamin supplements as described by Tepy and Elvehjem."

In the first series, the urinary excretion of pteroylglutamic acid was studied following the administration of various dosage levels of a solution of the sodium salt. Two experiments were included in which the excretion of the free acid suspended in water or oil was measured. The results, shown in Table I,

indicated that the proportion which was excreted increased as the dose was raised. The greater part of the excretion took place in the first six hours. A small part of the administered dose was excreted in the next eighteen hours. This is illustrated in the data in Table II. An average of 53 per cent of a

dose of 5 mg. was excreted in twenty-four hours, and an average of 90 per cent of this excretion took place in the first six hours. After twenty-four hours the urinary folic acid content returned to the basal level.

In the next series, the excretion of folic acid in the urine was studied following the administration of pteroyltriglutamic acid (pteroyl- γ -glutamyl- γ -glutamyl glutamic acid).¹⁰ This compound has about 3 per cent of the activity of pteroylglutamic acid in the *Str. faecalis* R assay. Urinary excretion values in excess of the total microbiologic activity of the administered dose were presumed to indicate that pteroyltriglutamic acid had been excreted as pteroylglutamic acid. The results, which are given in Table III, led to the conclusion that pteroyltriglutamic acid was readily hydrolyzed in the body to pteroylglutamic acid because the urinary excretion values following the administration of pteroyltriglutamic acid were very similar to those observed with pteroylglutamic acid.

TABLE III. AMOUNTS OF FOLIC ACID ACTIVITY FOUND PRESENT IN THE URINE FOLLOWING ADMINISTRATION OF 7.9 MG. OF PTEROYLTRIGLUTAMIC ACID (EQUIVALENT TO 5 MG. OF PTEROYLGLUTAMIC ACID) WHEN ADMINISTERED AS SOLUTION OF SODIUM SALT

There was some indication of a lag in excretion as evidenced by the proportion of the biologic activity excreted in the 6- to 24-hour period being greater with pteroyltriglutamic acid than with pteroylglutamic acid. An average of 15 per cent of the twenty-four hour excretion was found in the urine collected from the sixth to the twenty-fourth hour following dosage with pteroyltriglutamic acid as compared with 10 per cent following dosage with pteroylglutamic acid. The excretion rate, measured as pteroylglutamic acid, appeared to be the same following dosage by either the oral or intravenous route, which could lead to the assumption that the breakdown of pteroyltriglutamic acid to pteroylglutamic acid in the body could take place with equal rapidity whether or not the triglutamic compound passed into the body through the gastrointestinal tract.

Experiments were also made with pteroyldiglutamic acid (pteroyl- α -glutamyl glutamic acid).¹⁰ This compound has practically no activity in stimulating the growth of either *L. casei* or *Str. faecalis* R, so that any substantial increase of microbiologic activity in the urine could be attributed to pteroylglutamic acid formed by breakdown of pteroyldiglutamic acid in the body. The results are in Table IV. The data indicate that the body possesses the ability to liberate pteroylglutamic acid from pteroyldiglutamic acid. Even more than in the case of pteroyltriglutamic acid, there was a lag in the rate of excretion so that a comparatively large but variable proportion of the administered dose, measured

as pteroylglutamic acid, was found in the urine during the period between six and twenty-four hours after dosage. The effect was especially marked following intravenous administration.

The last compound studied was the diamide of pteroylglutamic acid.¹¹ This substance does not appreciably stimulate the growth of *L. casei* or *Str. faecalis* R. No increase in the urinary pteroylglutamic acid level was found in twenty-four hour samples following the oral administration of 10 mg. doses to three subjects. The compound was prepared from *p*-aminobenzoylglutamic acid diamide, 2,3-dibromopropionaldehyde, and 2,4,5-triamino-6-hydroxypyrimidine. Hydrolysis of the compound by autoclaving with 0.4 N NaOH for one hour at 130° C. resulted in the liberation of 69 per cent of the calculated quantity of pteroylglutamic acid, as measured by assay with *Str. faecalis* R.

DISCUSSION

The apparent ability of the body to hydrolyze pteroyldiglutamic acid, as evidenced by the urinary excretion data in the present investigation, is in contrast to the microbiologic inactivity of this substance but may be in harmony with its reported effect in producing a remission in macrocytic anemia.¹² The inactivity of pteroyldiglutamic acid for *L. casei* and *Str. faecalis* R may indicate that these organisms do not possess a "conjugase" system which is effective in hydrolyzing the peptide linkage in pteroyldiglutamic acid between the terminal glutamic acid and the α -carboxyl group of the glutamic acid radicle of the pteroylglutamic acid moiety of the molecule. In contrast, pteroyltriglutamic acid, in which the glutamyl radicles are linked through their γ -carboxyl groups, is fully active for *L. casei* which may mean that this organism has a "conjugase" system which hydrolyzes the γ linkage between glutamyl groups. An alternative explanation would be that *L. casei* utilizes both pteroylglutamic acid and pteroyltriglutamic acid, but not pteroyldiglutamic acid, as precursors of more complex substances.

The nature of the possible breakdown products of pteroylglutamic acid that are excreted in the urine is a matter of speculation. The presence of

xanthopterin in normal urine has been repeatedly noted and it is logical to infer that this substance may be formed by the breakdown of pteroylglutamic acid.*

The present study indicated that pteroyltriglutamic acid is rapidly absorbed following administration, for pteroylglutamic acid was excreted in the urine at approximately the same rate following either oral or intravenous administration of pteroyltriglutamic acid. The data also indicate that, as previously noted,⁵ pteroyltriglutamic acid is readily hydrolyzed to pteroylglutamic acid in the body. The site of this breakdown is not known, but preparations made from various organs have been shown to have "vitamin B₁₂ conjugase" activity¹² as indicated by liberation of pteroylglutamic acid from pteroylheptaglutamic acid. Certain enzyme preparations of this type, prepared from chicken pancreas, have been found readily to liberate pteroylglutamic acid from pteroyltriglutamic acid.¹⁴

The limited data in Table 1 appeared to indicate that, with a 5 mg. dose of pteroylglutamic acid, an oily vehicle appeared to depress the excretion and hence possibly the uptake of an oral dose; also, the rate of excretion following the administration of a solution of the sodium salt was somewhat higher than when a suspension of the free acid was used.

CONCLUSIONS

1. The urinary excretion of folie acid, as measured by assay with *Str. faecalis* R, was studied with normal subjects receiving various dosages of pteroylglutamic acid (PGA), pteroyltriglutamic acid, and pteroyldiglutamic acid.

2. The proportion of the administered dose of pteroylglutamic acid which was excreted was found to increase as the dose was raised.

3. With pteroylglutamic acid most of the excretion took place within the first six hours, a small part of the administered dose was excreted in the next eighteen hours, and after twenty-four hours the excretion returned to the basal level of between 5 and 10 millimicrograms per milliliter.

4. The microbiologic assay data indicated that pteroyltriglutamic acid was readily hydrolyzed to pteroylglutamic acid in the body when administered by either the oral or intravenous route.

5. Similar results were observed following the administration of pteroyldiglutamic acid. A slight lag in the excretion rate observed with pteroyltriglutamic acid was somewhat more marked in the case of pteroyldiglutamic acid.

6. No increase in the urinary pteroylglutamic acid level was found following the administration of the diamide of pteroylglutamic acid.

The collaboration of Mr. J. Van Meter in assisting with the microbiologic assays is gratefully acknowledged.

*Recently it has been reported by Denko (paper presented at the One Hundred Twelfth Meeting of the American Chemical Society, New York, September, 1947) that, following oral administration of 10 mg., the apparent urinary excretion of pteroylglutamic acid as measured with *L. casei* in some cases far exceeded the dose. No such observation was made in the present study, using *Str. faecalis* R.

ANOMALOUS FINDINGS IN PENICILLIN LEVEL DETERMINATIONS IN URINE

CAROLYN R. FALK, B.A., AND HELEN BLECH, B.A.
NEW YORK, N. Y.

INTRODUCTION

NUMEROUS investigators (including Florey and co-workers,² Rammelkamp and associates, 1943,^{3,4} Free and co-workers, 1944,⁵ Mutch and Rewell, 1945,⁶ McDermott and associates, 1946,⁷ and Eagle, 1947⁸) have shown that from 60 to 100 per cent of the penicillin administered in a single dose may be voided during the first four hours after injection.

However, in the course of determining penicillin levels in a series of urine specimens obtained from patients under treatment for syphilis, unexpectedly high values were observed in a number of urines collected up to the fourth hour following the administration of penicillin. This report deals with the results obtained from a study of these specimens tested for streptococidal action at regular intervals over a three-month period. Since these findings were in excess of what could be explained by the dose injected, some of the factors influencing the test also will be discussed.

MATERIALS

The urines tested were sent to the laboratory for routine penicillin assay.* All specimens were refrigerated from time of collection, although a delay of several days until time of assay was frequent. The volume of the samples varied from 50 to 100 milliliters. Unfortunately, the exact volume voided at one time was recorded in only a few instances.

METHODS

Assays were made by the Rammelkamp method.⁹ The samples were filtered through a Seitz filter immediately upon reception at the laboratory, to insure sterility. Before assay, appropriate preliminary dilutions of the urine were made in phosphate buffer pH 6.0, so that an end point would be obtained by the use of not more than fifteen serial dilutions.

The test organism was a Group A hemolytic streptococcus, Strain 98.† This strain was regularly sensitive to between 0.0039 and 0.0078 Oxford units of penicillin per milliliter.

The sample and culture dilutions were made in beef heart broth pH 7.0 to which 50 mg. per liter of para-aminobenzoic acid had been added. The tests and dilution tubes were kept in an ice bath during the execution of the test.

EXPERIMENTAL RESULTS

None of the specimens of urine tested before treatment was initiated showed streptococidal action equivalent to more than 0.04 unit of penicillin.

From the Bureau of Laboratories, Department of Health.

Presented at the Forty-seventh General Meeting of the Society of American Bacteriologists, Philadelphia, Pa., May 13-16, 1947.

Received for publication, Aug. 7, 1947.

*By Dr. Alfred Cohn, Venereal Disease Research Division.

†Obtained through the courtesy of Dr. Rammelkamp.

Furthermore, 249 specimens collected from 5 to 143 hours following drug administration showed both reproducible and reasonable assay values. However, these conditions did not prevail in many specimens collected up to the fourth hour following treatment. Anomalous findings were first observed in this group of specimens in a series of six individuals tested in May, 1946. In the initial assay seven of twelve specimens showed levels from five to one thousand times higher than was anticipated. During a period of five weeks' storage another seven of twelve specimens showed an increase in titer from ten to one hundred fold over the initial test. Only one specimen failed to show increased bactericidal action at some time during this period. These results were observed when the subjects were given penicillin in saline, as well as in water and oil emulsion.

Tables I and II show typical protocols. Patient D. B. (Table I) received one injection of 150,000 Oxford units of penicillin in saline solution. Specimens were collected two, four, eight, twelve, and twenty-four hours following the administration of the antibiotic. These samples were tested at weekly intervals over a period of one hundred days. In instances where more than one test was made during a given period of time, the figures represent an average of the results. All figures represent units per milliliter. Each individual specimen contained between 50 and 100 milliliters. The two-hour sample showed a recovery of 4,000 units of penicillin per milliliter. This would mean that the entire sample contained between 200,000 and 400,000 Oxford units, which was more than the amount administered. Furthermore, during the third week of storage, assays showed that the level per milliliter was equivalent to the entire dose injected, and the level increased tenfold more during the following three weeks. Subsequently it dropped to anticipated levels. Specimens collected on the fourth, eighth, twelfth, and twenty-fourth hour showed regular and reproducible results.

TABLE I. PENICILLIN LEVEL DETERMINATION (PATIENT D. B.; DIAGNOSIS, SYPHILIS; PENICILLIN ADMINISTERED, 150,000 O. U. IN SALINE)

DAYS' STORAGE (5° C.)	TIME OF URINE COLLECTION AFTER ADMINISTRATION OF PENICILLIN (HR.)

59 to 78	1,300	65	5.0	--	--
100	500	40	2.5	0.31	--

Patient D. (Table II) received one dose of 1,000,000 Oxford units of penicillin in saline solution. Again more antibiotic action than would be expected from the treatment given was found in the two- and four-hour samples. Similar observations were made on tests made during the first five weeks after collection. However, these same specimens showed normal levels from the sixth through the fourteenth week. Tests on the eight-, twelve-, and twenty-four hour specimens again showed regular and reproducible results.

TABLE II. PENICILLIN LEVEL DETERMINATION (PATIENT D.; DIAGNOSIS, SYPHILIS; PENICILLIN ADMINISTERED, 1,000,000 O. U. IN SALINE)

DAYS' STORAGE (5° C.)	TIME OF URINE COLLECTION AFTER ADMINISTRATION OF PENICILLIN (HR.)

61 to 100	5,000	75	40	2.5	--

In October and November, 1946, the one-hour urine specimens of another six subjects who received a single dose of 1,000,000 Oxford units of penicillin in water and oil emulsion were studied. As before, the total volume varied between 50 and 100 ml. per sample. Table III shows the results obtained per milliliter in four typical instances. The general pattern of the early specimens tested in May was repeated. Specimens obtained from these individuals immediately preceding treatment showed no bactericidal activity. Furthermore, the activity of the one-hour specimens was completely destroyed by the use of the penicillinase broth.

*Squibb penicillin 12003-1; expiration date, April 1, 1947.

The possibility that certain specimens might contain a substance capable of producing a synergistic effect in the presence of penicillin was then investigated. Accordingly, 10,000 Oxford units of a commercial penicillin per milliliter were added to a 10 c.c. portion of pretreatment urine. This sample was then tested at the same time as a specimen collected from this same subject one hour after treatment was started.

Results of these comparative tests are shown in Table IV. The one-hour specimens again showed potentiated bactericidal activity, while the pretreatment urine to which 10,000 Oxford units of penicillin per milliliter were added showed regular and reproducible results which were similar to the result obtained when an equivalent amount of penicillin was diluted with phosphate buffer at pH 6.0. Again the untreated pretreatment urine showed no bactericidal activity, and the addition of penicillinase to either the one-hour urine sample or the penicillin in buffer solution destroyed the activity of the test sample.

*Squibb penicillin 12005-1; expiration date, April 1, 1947.

It may be considered that these results were caused by a technical error in the method of dilution of the test samples. Experiments were therefore set up using different initial dilutions, different dilution volumes, and different diluents. No significant variations were observed.

To ascertain whether the high levels were caused by experimental accidents, twenty-four different one-hour specimens* were divided each in three aliquot parts and tested at regular intervals for a period of six weeks. Again, there was never more than a twofold variation between the different portions of any one specimen.

It was thought that the delay of twenty-four or more hours between the time of collection of the specimens and the time of assay might be a contributing factor in producing the phenomenon of enhanced bactericidal activity. To investigate this possibility, the previously mentioned twenty-four specimens collected one hour after the administration of 1,000,000 O.U. of penicillin in Pendil-beeswax were filtered and tested within one hour after excretion. All tests were carried out in triplicate over a six-week period. During this period there were no significant changes in titer in any of the twenty-four samples.

COMMENTS AND CONCLUSIONS

In a study of sixty-seven early specimens of urine anomalous findings have been observed in thirty instances. These results did not appear to be caused by the usual technical errors in experimental accidents. Furthermore, the

*Twenty-one specimens from patients receiving 1,000,000 O.U. Heyden penicillin #1276 (expiration date, Aug. 1, 1948) diluted in Pendil-beeswax; three specimens from patients receiving 1,000,000 O.U. Parke Davis penicillin #02314A (expiration date, July, 1948) diluted in Pendil-beeswax.

phenomenon of increased bactericidal action was not observed in any of the 249 specimens collected more than four hours after treatment.

No explanation for this phenomenon has been found. It is reported, at this time, to call attention to irregularities that may be encountered in attempting to make a quantitative estimate of the penicillin content of early urines.

We wish to thank Dr. Alfred Cohn and Dr. Isank Grunstein, of the Venereal Disease Research Clinic, for their cooperation in obtaining early specimens of urine, and Mrs. Shirley Tove and Miss Mildred Schleimer for technical assistance.

THE ANTIBACTERIAL ACTIVITY OF SOME SULFON- AND SULFANILANILIDE DERIVATIVES

G. R. GOITCHUIS, M.S., AND C. A. LAWRENCE, PH.D.

RENSSELAER, N. Y.

AN EARLIER communication¹ from these laboratories presented the general antibacterial activity of a series of benzenesulfonic acid derivatives. The most effective compound there referred to was found to be 3',5'-dibromosulfanilamide or the corresponding dichloro derivative. The removal of the amino group resulted in only a slight loss in activity. Several monohalogenated and dihalogenated compounds were tested in which the bromine or chlorine atoms were placed in various positions on the anilide portion of the molecule. Antibacterial activity was practically lost when a halogen was placed in the 2-position. While all these compounds displayed definite antibacterial action, none approached that of 3',5'-dibromosulfanilamide. The latter compound was also tested for antibacterial properties against pathogens, most of which cause infections which do not readily respond to present chemotherapeutic agents.²

In order to obtain a better correlation between chemical structure and degree of antibacterial action, it seemed worth while to prepare additional benzenesulfonic acid derivatives. Accordingly, the following compounds* were tested by the present authors.

COMPOUND	NAME	MOL. WEIGHT
1	2',6' dichlorosulfanilamide	302.2
2	3',5'-dibromo 4'-hydroxybenzenesulfonamide	407.0
3	3',5'-dibromo 4'-hydroxysulfanilamide	422.1
4	3' bromo 5' chloro-4' hydroxysulfanilamide	377.6
5	3' bromo 5' chlorosulfanilamide	361.6
6	3',5' diodo 4' hydroxysulfanilamide	516.0
7	3',5'-diiodosulfanilamide	500.0
8	3',5'-bis-(trifluoromethyl) sulfanilamide	384.3
9	3' trifluoromethylsulfanilamide	316.3
10	3',5' dibromo o aminobenzenesulfonamide	406.1
11	3',5' dibromo m aminobenzenesulfonamide	406.1
12	N ⁴ succinyl 3',5' dibromosulfanilamide	506.2
13	3',5' dibromosulfanilamide	406.1

METHODS

The method for testing the antibacterial action of the compounds was essentially the same as that outlined in the previous report.¹ This consisted of dissolving the drugs in a few c.c. of alcohol preparatory to making an initial dilution in nutrient broth. Serial dilutions were prepared in broth from 1:1,000 up to and including 1:1,024,000. After autoclaving, the drug broth mixtures were inoculated with a test organism and incubated at 37° C. for seventy two hours. Tubes containing no growth or growth less than one half that of the drug-free control after incubation for twenty four hours (forty eight hours in test with *Actinomyces bovis*) were considered to contain a bacteriostatic concentration of drug. All

tubes in which growth failed to appear after incubation for seventy-two hours were subcultured into fresh drug-free broth, and the subculture tubes incubated for an additional seventy-two hours. Failure of growth to develop in the latter was taken as evidence of a bactericidal action in the tubes from which they were subcultured. Bacteriostatic and bactericidal action against the gonococcus was determined by subculturing on dextrose-starch agar.* In the study, 3',5'-dibromosulfanililide (Compound 13) was included for purpose of comparison. The results of this investigation are presented in Table I.

RESULTS

The only compound which appears to approach or to exceed the activity of 3',5'-dibromosulfanililide (compound 13) is a derivative containing a large number of fluorine radicals (compound 8). The iodo analogue (compound 7) of compound 13 and the 5-bromo-3-chloro derivative (compound 5) appear to exert an activity comparable to that of the parent compound. The introduction of the hydroxyl group on the 4-position of the anilide invariably results in a decrease of activity (compare compound 3 with 13, 4 with 5, and 6 with 7). The succinyl derivative (compound 12) also displays a marked decrease in antibacterial action.

The ortho- and metaisomers (compounds 10 and 11) present an action equal to that of 3',5'-dibromosulfanililide when all the test organisms are collectively taken into consideration. This would tend to indicate that a free amino group in the para-position is not essential for maximum activity, and may thus explain why the action of 3',5'-dibromosulfanililide against *Streptococcus pyogenes* is unaffected by the presence of p-aminobenzoic acid.

SUMMARY

Several new derivatives of 3',5'-dibromosulfanililide have been prepared and tested for antibacterial action in vitro against type I pneumococci, *Streptococcus pyogenes* (C203), *Streptococcus faecalis*, *Streptococcus viridans*,

*Difco Laboratories, Inc., Detroit, Mich.

Staphylococcus aureus, *Neisseria gonorrhoeae*, *Clostridium welchii*, *Brucella abortus*, *Hemophilus ducreyi*, *Pasteurella pestis*, *Vibrio cholerae*, and *Actinomyces bovis* (anaerobic).

The 3',5'-bis-(trifluoromethyl) derivative was found to be somewhat superior to 3',5'-dibromosulfanililide, while the 3',5'-diiodo and the 3'-bromo-5'-chloro derivatives were about equal to 3',5'-dibromosulfanililide in antibacterial action.

The ortho- and meta-isomers in which the NH₂ group is not in the para-position display an activity equal to 3',5'-dibromosulfanililide, while the hydroxysulfanililide and succinyl derivatives which were tested were found to be less active than the latter compound

Since this paper was prepared, Schmidt and Sesler³ demonstrated that 3',5' dibromo sulfanililide and a series of derivatives therefrom held little promise as effective chemotherapeutic agents in bacterial infections. McChesney⁴ more recently described the toxicity, absorption, and metabolism of 3',5' dibromosulfanililide which account for its relative ineffectiveness in infection protection tests in experimental animals

THE EFFECT OF 2,3-DIMERCAPTOPROPANOL (BAL) ON THE TOXICITY OF GOLD

STANLEY LEVEY, PH.D., AND CHARLEY J. SMYTH, M.D.

ELOISE, MICH.

BAL (2,3-dimercaptopropanol) was first introduced as an agent capable of combating the arsenic toxicity which results from Lewisite burns.¹ In addition to reducing the toxicity of compounds of arsenic,² this sulfhydryl compound has been shown to diminish the toxicity of antimony,³ mercury,³ chromium,³ bismuth,³ and nickel.⁴

Gold compounds have found rather widespread clinical use in the treatment of rheumatoid arthritis. However, due to the toxicity of this heavy metal, extreme caution is required in its therapeutic use. The purpose of this study was to determine in experimental animals whether some of the gold compounds commonly used as therapeutic agents could be rendered less toxic by the use of BAL.

While this work was in progress there appeared a series of papers covering the effect of BAL on the toxic symptoms produced by gold in human subjects.⁵⁻⁷ Ragan and Boots⁸ mentioned that BAL reduces the toxicity of gold in rats, but few data were presented.

METHODS

For acute toxicity studies, groups of adult hooded rats, varying in weight from 190 to 326 grams, were given one of the gold compounds studied. All administrations were made intramuscularly and the survival time was recorded. The dose of the gold compound administered was that which was determined by preliminary trial to cause death within a few days. One control group of animals received only the gold compound. A second (test) group received the same dose of the same gold compound in one thigh and BAL in the muscle of the opposite leg. Additional groups of rats received the same dose of gold, but the BAL was administered in multiple doses. Any change in the survival time was considered to be due to the modification of the toxicity of the gold compound tested.

In the studies of the effect of gold and BAL on the rate of growth of young rats, all the animals except those which received neither gold nor BAL were litter mates. In this portion of the experiment the animals received a single sublethal dose of gold and also a single dose of BAL. Weights usually were recorded every second day during the early portion of this work; later a longer time interval was used. Growth was recorded for a period of twenty-three days. At the end of this period the animals were sacrificed and portions of the liver and kidney were fixed in formalin for microscopic examination.

From the Departments of Physiological Chemistry and Medicine, Wayne University College of Medicine, Detroit, and the Wayne County General Hospital, Eloise, Mich.

Received for publication, July 3, 1947.

The toxicities of the following gold-containing compounds were studied: gold sodium thiosulfate, gold sodium thiomalate (Myochrysine*), sodium succinidoaurate,† and gold thioglucose.‡ The last substance was supplied both as a pure solid and as a suspension in an oily medium. A commercial 10 per cent solution of BAL in oil and benzyl benzoate was used.

It was found that if an aqueous solution of BAL was added to an aqueous unbuffered solution of either gold sodium thiosulfate or gold sodium thiomalate a heavy yellow precipitate formed immediately. In the case of sodium succinidoaurate and gold thioglucose no precipitate formed on mixing solutions of these compounds with aqueous BAL. The BAL-gold compound proved to be insoluble in water, dilute HCl or NaOH, alcohol, and ether. The BAL-gold compound formed with either gold sodium thiomalate or gold sodium thiosulfate was washed successively with water, alcohol, and ether, and dried in a vacuum desiccator over sulfuric acid. The content of gold in each sample was determined by ashing according to the method of Pregl⁴ and by weighing the gold residue. In addition, a sample of the BAL-gold compound containing two atoms of gold per molecule of BAL was prepared according to the procedure of Weiss⁵ by adding one mol of gold bromide to 0.8 mol of BAL. The analyses of the compounds are given below:

BAL-gold compound from gold sodium thiosulfate	72.6 per cent Au
BAL-gold compound from gold sodium thiomalate	73.7 per cent Au
BAL-gold compound from gold bromide	73.6 per cent Au
Theoretical $C_3H_2O_2SAu_2$	76.4 per cent Au

These analyses indicate that the compounds formed are about 95 to 96.5 per cent pure. The probable structure for the BAL-gold compounds is:

RESULTS

Gold sodium thiosulfate was found to be a toxic compound. Six groups of animals were studied. The results of this experiment are summarized in Table I. Rats given this compound in doses equivalent to 75 mg. of gold per kilogram usually died within six hours. The administration of 12.5 mg. of BAL just before the gold sodium thiosulfate appeared to reduce the toxicity of the gold compound by about one-third. The survival time of the rats was the same whether a single dose of BAL was given either one minute before or one hour after the gold. If two doses of BAL were given, one a minute after the gold and the second five hours later, there was a prolongation of the survival time as compared with a single dose of BAL. Four of the ten animals in this series survived the test period of fourteen days and then were sacrificed. If three doses of BAL were administered at 1-minute, 3-hour, and 6-hour intervals after the gold, the effects were in general similar to those obtained with two doses of BAL. However, only two of the animals in this group survived the period of study. The animals which survived only about six hours probably died of respiratory and vasomotor paralysis.¹⁰ The animals which lived three to six

*s. The animal survived for the experimental period of fourteen days.

days showed large soft, grayish spotted kidneys on death. Microscopic examination of the kidney showed extreme damage to the tubules of this organ. Renal insufficiency was believed to be the cause of death.

In the study of acute toxicity, gold sodium thiomalate was administered to six groups of animals. The results of these experiments also are summarized in Table I. The amount of gold used in the first group of animals in this series was equivalent to that used in the gold sodium thiosulfate study (75 mg. per kilogram). Survival time for the animals treated with gold sodium thiomalate was considerably longer than that observed with gold sodium thiosulfate. The administration of BAL immediately after giving gold sodium thiomalate did not appear to have any effect on the survival time of the animals. In the remainder of this study, the dose of gold sodium thiomalate was increased to the equivalent of 100 mg. of gold per kilogram in order to decrease the survival time of the animals. Thus, any detoxifying effect of BAL could be more easily detected. The administration of 12.5 mg. of BAL to animals five minutes after the dose of gold appeared to have no effect on the survival time. If two doses of BAL were given, one three hours and the other twenty-four hours following the gold, there was no prolongation of the survival time as compared with the control animals of this series. If three doses of BAL were given, one immediately after the gold, the second four hours later, and the last seven hours after the gold, there was a slight decrease in the length of their survival. This effect may have been due to the sum of the toxicities of BAL and gold.

The toxicity of sodium succinimidoaurate can be effectively reduced by the administration of BAL after the gold compound. Table 1 shows that, following administration of the BAL, there were no deaths due to gold.

An attempt was made to produce death in rats by administering gold thioglucose which was supplied in an oil media, but the dose required to produce death consistently was too high to have value in this study. Four of the rats received as much as 2 ml. of the oily suspension which contained 200 mg. of gold (approximately 800 mg. per kilogram). Two of the animals survived and two died, one on the third and one on the fifth day after injection. At autopsy, the animal that lived only three days had a large mass of yellow oil at the site of injection, showing that the absorption of the gold compound was poor. On the other hand, if an aqueous solution of gold thioglucose was administered in a dose supplying 100 mg. of gold per kilogram, the animals usually died within four days. Three doses of BAL completely protected the animals, as shown by survival of all seven animals tested.

Fig. 1.—The effect of a single dose of gold sodium thiomalate on the growth of young rats. The dose of gold was 50 mg. per kilogram and that of BAL 3.1 mg. per animal. These compounds were given intramuscularly, at the start of the experiment. The numbers along the left border are the initial weight in grams and those on the right are the final weight twenty-three days later.

The effect of BAL on the rate of growth of rats given a nonlethal dose of gold (50 mg. per kilogram) was considered a more sensitive test than the survival time. The young rats which received the single dose of gold sodium thiomalate had rather shallow growth curves, while those which received the

same dose of gold plus BAL (3.1 mg.) had growth curves of approximately the same slope as those which received no treatment or only BAL (Fig. 1). Microscopic examination of the livers and kidneys of these animals was made. The kidneys of those animals which received only the gold showed "marked cloudy swelling of the proximal convoluted tubules with karyolytic and karyorrhectic nuclear changes and plugging of the tubules with necrotic debris some of which contains calcium. There are evidences of regenerative epithelial hyperplasia of the cells of these tubules. There is marked cloudy swelling and nuclear degeneration of scattered liver cells."⁶ Those which received the gold followed by the BAL showed "moderate cloudy swelling of the cells of the proximal convoluted tubules. A few basophilic hyaline casts are seen."⁶ BAL alone produced a similar picture.

DISCUSSION

In this study of the effect of BAL on the toxicity of various gold compounds, it is of interest that the gold compounds were of different chemical classes. The gold sodium thiosulfate contained monovalent gold bound in an inorganic linkage. Gold sodium thioglucose and gold sodium thiomalate contained monovalent gold bound to an organic radical. The attachment of the gold to the carbon chain was through a sulfur linkage. Sodium succinimidoaurate contained trivalent gold bound in a sulfur-free organic compound.

The data presented in Table I show that, under the conditions described, BAL reduces the toxicity of gold with all compounds tested except gold sodium thiomalate. It should be noted that the doses of gold used in the acute toxicity studies were relatively high. If smaller doses of gold sodium thiomalate were given and growth (as measured by an increase in weight) was used as a criterion of toxicity, BAL effectively detoxified gold sodium thiomalate.

When BAL was given with large doses of gold sodium thiosulfate the animals usually survived the factors which produced rapid death, but some of them later succumbed to the nephrotoxic effect of the heavy metal. This action also has been noted where the effect of BAL on cadmium poisoning was studied.⁴ The explanation given was that the BAL-metal compound is reabsorbed by the kidney tubule and produces toxic action there.

SUMMARY

The effect of BAL on the survival time of rats given subcutaneous injections of lethal doses of gold, as gold sodium thiosulfate, gold sodium thiomalate, gold thioglucose, or sodium succinimidoaurate was studied. BAL caused an increase in survival time with all compounds studied except gold sodium thiomalate. With sublethal doses of gold sodium thiomalate, BAL has a definite effect in reducing toxicity of this heavy metal when growth was used as a criterion.

HISTAMINE ANTAGONISTS

VIII. N-(α -PYRIDYL)-N-(α -THIENYL)-N',N'-DIMETHYLETHYLENEDIAMINE, A NEW ANTIHISTAMINIC COMPOUND. EXPERIMENTAL AND CLINICAL EXPERIENCES

SAMUEL M. FEINBERG, M.D., AND THEODORE B. BERNSTEIN, M.D.
CHICAGO, ILL.

A NEW antihistaminic drug of the ethylenediamine series, N-(α -pyridyl)-N-(α -thienyl)-N',N'-dimethylethylenediamine hydrochloride, made available to us about a year ago,^{*} has been found to possess potent clinical and pharmacologic activities. This substance differs from pyribenzamine in the substitution of a thienyl for the benzyl ring and has the following structural formula¹:

EXPERIMENTAL FINDINGS

This substance is similar to most of the other antihistaminic drugs in its local anesthetic action. It was found to be a potent antihistaminic substance. Death in guinea pigs from an intravenous M.L.D. 100 dose of histamine† (0.4 mg. histamine base per kilogram) could be prevented in 100 per cent of the animals by the intraperitoneal injection thirty minutes previously of 0.1 mg. of the drug per kilogram. A dose of 0.05 mg. per kilogram protected 50 per cent of the animals. Roth and associates² found that 5 mg. of the drug per kilogram intraperitoneally was effective in protecting guinea pigs against 60 M.L.D. 100 of histamine, while Ereoli and associates³ obtained protection against 150 to 200 lethal doses of histamine by using 10 to 15 mg. of the drug per kilogram.

Roth and associates report that 0.002 γ per cubic centimeter produces 75 per cent or greater inhibition of the contraction of the guinea pig ileum from 0.005 γ per cubic centimeter of histamine base. The activity of this drug in the inhibition of the ileal contraction, as compared with other drugs, is esti-

From the Department of Internal Medicine, Division of Allergy, Northwestern University Medical School.

This study was made possible by grants from Eli Lilly & Co., Indianapolis, Ind., Abbott Laboratories, North Chicago, Ill., and the National Health Institute of the United States Public Health Service.

Received for publication, Aug. 27, 1947.

*The drug was submitted to us by the research departments of Eli Lilly & Co., Indianapolis, Ind. (Histadyl), and of Abbott Laboratories, North Chicago, Ill. (Thienylene), without either firm being cognizant until several months later that both had synthesized the same compound.

†Histamine diphosphate supplied through the courtesy of Burroughs Wellcome & Co., Inc., New York, N. Y.

mated by Lee and associates⁴ as follows: benadryl, 1; pyribenzamine, 4.9; and the thienyl compound, 3.9. Such active inhibition also was found by Ereoli and associates³ and by us.

Protection against death from aerosolized histamine was studied by Lee and associates, who found the drug six times more potent than benadryl and less than half as potent as pyribenzamine. Ereoli and associates³ also reported effective protection against histamine aerosol.

Our work along this line was somewhat different. Because of our special interest in the possible therapeutic value of aerosols of antihistamine drugs in asthma, we wished to study the effect of such drug aerosols as protection against bronchospasm from aerosolized histamine. In order to approximate conditions more closely resembling those in human asthma we selected unquestioned labored breathing, rather than death, as the end point in the guinea pig. The animals were exposed for five minutes to a standard aerosol of the drug in one chamber, and after a period of fifteen minutes they were exposed to the standard histamine aerosol. The time elapsing before the onset of dyspnea was noted. By varying the concentrations of the drug aerosol on different days in the same series of animals a fair estimate of the protective ability of the drug could be made. Many experiments with many variations were performed and comparative studies of all available drugs were made. The complete details will be reported at another time. Here we wish to note briefly that moderate concentrations of the drug aerosol ($\frac{1}{2}$ to 2 per cent), for five minutes at 5 pounds pressure with a particular atomizer were effective in giving appreciable protection against histamine aerosol ($\frac{1}{2}$ mg. of base per cubic centimeter at 5 pounds pressure). This protection was not quite as good as that obtained with pyribenzamine, but better than that obtained with benadryl.

The intraperitoneal injection of 1 mg. per kilogram of this drug in guinea pigs was effective in protecting ten of ten animals against anaphylactic death, while a large control series showed a mortality of 61 per cent.

CLINICAL FINDINGS

The thienyl compound has been found by us to be an effective remedy in the symptomatic relief of allergic manifestations. In 112 patients with seasonal hay fever (including that due to the pollen of trees, grasses, and weeds, and to the spores of molds) seventy-nine, or 70 per cent, were benefited. Of ninety-five patients with nonseasonal vasomotor rhinitis, forty-four, or 46 per cent, received some measure of relief. The dyspnea of asthma was not appreciably altered in thirty patients, although the preasthmatic, spasmodic cough was decidedly helped in six of nine patients. The subjective symptoms of urticaria were helped in seven of twelve patients. In thirteen patients with atopic dermatitis eight obtained considerable relief from the itching. Seven of nine patients with dermatographism and one with pruritus of unknown origin were benefited. Pruritus ani was substantially relieved in two of three patients. The experimental wheal produced by histamine or by a specific antigen on the human skin was diminished by the local application of the drug.

As with other previously described antiallergic drugs with antihistaminic action,^{5, 6} the relief was only palliative, lasting two to six hours, was not complete, since all manifestations of the allergic ailment were not abolished, and was not obtained in all allergic patients. From our experience thus far, we gain the impression that this drug is an effective agent in the alleviation of allergic manifestations, particularly allergic rhinitis and itching dermatoses. Although the incidence, and perhaps the degree, of relief is not quite as high as that obtained with pyribenzamine, the thienyl compound has the common attribute of other antihistaminic compounds in its selective superiority for particular individuals. In other words, in some patients this drug is more effective than other drugs with a higher therapeutic index.

The average dose of the drug is 50 mg. orally, one to four times daily, depending on the nature of the manifestations. In a few patients we employed 100 mg. doses, but these were frequently not well tolerated. In 253 patients, most of whom received 50 mg. doses, undesirable side actions were noted in sixty-three, or 25 per cent. Sedation was the most common finding, occurring in forty-eight, or 19 per cent, of the patients. The degree of sedation was not as great as that produced by benadryl, but approximated or perhaps exceeded that experienced with pyribenzamine. Our limited use of 100 mg. doses gives us the impression that marked sedation is probably more common than with similar doses of pyribenzamine. Here again, as with therapeutic individuality, we found individuality in sedative effects. We encountered patients who experienced sedation from pyribenzamine and no sedation from the thienyl compound. Other but less frequent side actions noted were vertigo, nervousness, dryness of the mouth and throat, excitation, insomnia, headache, nausea, and diarrhea.

SUMMARY

1. A new antihistaminic compound, N-(α -pyridyl)-N-(α -thienyl)-N',N'-dimethylethylenediamine hydrochloride, is a potent agent in the prevention of death from histamine injection or aerosol in the guinea pig, in the inhibition of the histamine contraction of the guinea pig ileum, and in the prevention of anaphylactic shock.

2. Aerosols of this drug are capable of preventing bronchospasm and dyspnea in guinea pigs from aerosolized histamine.

3. This drug has a high incidence of effectiveness in the symptomatic relief of some allergic conditions, particularly allergic rhinitis (seasonal and nonseasonal), urticaria, and atopic dermatitis.

4. Side reactions are fairly common and consist mainly of sedation. In degree and incidence sedation is less than that obtained with benadryl and equals or exceeds that of pyribenzamine.

5. The general experimental and clinical efficacy of this drug approaches but does not equal that of pyribenzamine. However, its availability is an advantage because in selected persons it is more effective or less disturbing than pyribenzamine.

6. Neither this nor any other antihistaminic drug has any but palliative function and does not replace the more basic and more lasting benefit obtained from allergic management by avoidance or desensitization.

EFFECT OF ALKALOIDS ON ACETYLCHOLINE AND POTASSIUM SENSITIVITY OF STRIATED MUSCLE

CLARA TORDA, PH.D., M.D., AND HAROLD G. WOLFF, M.D.
NEW YORK, N. Y.

IN A study dealing with the mechanism through which muscle shortening is induced, data about agents that modify the induction of muscle shortening may be essential.

In the following, the effects of various concentrations of different alkaloids on the shortening of striated muscle induced by acetylcholine and potassium were investigated.

EXPERIMENTAL

Effect of Alkaloids on Acetylcholine Sensitivity of Striated Muscle.—

Method: The rectus abdominis muscle of the frog was excised and suspended in a muscle chamber containing 10 c.c. frog Ringer's solution. Shortening of the muscle was induced throughout the experimental procedure by immersion in Ringer's solution containing acetylcholine bromide (50 μ g per 100 c.c.) for two minutes. Between two immersions in acetylcholine the muscle was washed with Ringer's solution for ten minutes. This procedure was repeated until three successive immersions in the solution of acetylcholine gave similar responses. The shortening of muscle was registered by an isotonic lever on a kymograph. After this stabilization, between two shortenings induced by the acetylcholine solution, instead of washing with Ringer's solution for ten minutes, the muscle was washed for five minutes and was immersed for five minutes in Ringer's solution containing one of the alkaloids to be investigated. Solutions containing the alkaloids in increasing concentrations were used. The pH of all solutions was corrected to 7.

Control: Muscles were immersed only in Ringer's solution and shortening was induced with the acetylcholine solution as described. The repeatedly induced shortenings, each lasting two minutes, were of the same magnitude for at least three hours. This period of time was longer than the duration of the experiments described.

Calculation: The amount of shortening of muscle after immersion in the various solutions to be tested was expressed as a percentage of the amount of shortening of the same muscle induced by acetylcholine before immersion in the solution of alkaloids. All results deviating from 100 per cent by more than twice the square root of the sum of the squares of the standard error of mean of the controls and the standard error of mean of the experiments were considered significant [$2 \sqrt{S.E.^2 \text{ (control)} + S.E.^2 \text{ (experiments)}}$].

Results: The effects of the alkaloids on the shortening of the rectus abdominis muscle induced by acetylcholine are given in Table I. The muscle shortening increased in the presence of physostigmine, colchicine, epinephrine, ergotamine, pilocarpine, morphine, and yohimbine (the latter three in higher concentrations). The other alkaloids used decreased the acetylcholine sensitivity of the muscle.

Effect of Alkaloids on Potassium Sensitivity of Striated Muscle.—In the following experiments the effect of the alkaloids on the shortening of muscle

From the New York Hospital and the Departments of Medicine (Neurology) and Psychiatry, Cornell University Medical College.

This study was aided by a grant from the John and Mary R. Markle Foundation.

Received for publication, July 19, 1917.

induced by potassium was investigated to ascertain whether the alkaloids modify the sensitivity of muscle to chemical stimuli other than acetylcholine.

Method: Shortening of muscle was induced by a 20 mM KCl solution instead of acetylcholine, and the effect of the substances on the potassium sensitivity of the muscle was observed as described previously.

Results: The results are given in Table I. The shortening of muscle induced by potassium increased in the presence of all alkaloids (except epinephrine and cocaine), veratrine and colchicine being the most effective agents. The potassium sensitivity decreased in the presence of epinephrine and cocaine and in the presence of higher concentrations of d-tubocurarine, strychnine, quinine, quinidine, and atropine.

*Each value represents the average of ten separate experiments. The S. E. of the mean for each value was less than ± 4 per cent.

†S. Shortening of the muscle occurred during the immersion of the muscle in the solution for five minutes, without addition of acetylcholine or potassium.

DISCUSSION

Shortening of muscle induced by acetylcholine and by potassium involves mechanisms not identical in all details. Acetylcholine and potassium induce different physicochemical changes in the muscle cells²⁻⁶ and even different physical changes in isolated myosin. Acetylcholine sensitivity parallels in many respects the sensitivity of muscle to indirect stimulation, whereas potassium sensitivity often parallels the effect of direct stimulation.⁷

The alkaloids used can be divided into two groups according to their effect on acetylcholine sensitivity: alkaloids increasing the acetylcholine sensitivity of striated muscle and alkaloids with a curarelike effect of decreasing the acetylcholine sensitivity.

The acetylcholine sensitivity of striated muscle was increased by at least two mechanisms: decrease of the activity of cholinesterase^{1,17} and direct effect on the striated muscle. That alkaloids exerted a direct effect on the muscle cell may be concluded since changes of acetylcholine sensitivity often did not parallel the degree of inhibition of the activity of cholinesterase,^{1,17} and the alkaloids modified the potassium sensitivity of the muscle.

The decreased potassium sensitivity of muscle immersed in epinephrine was, at least partly, due to the fact that epinephrine reduces the potassium content of the muscle cell (as documented by Torda and Wolff¹). Because d-tubocurarine, in higher concentrations, disintegrates the actomyosin fibers¹⁸ and also decreases the activity of adenosinetriphosphatase,¹⁹ it is likely that the decreased potassium sensitivity of the muscle in the presence of d-tubocurarine was, at least partly, due to these mechanisms.

Curare, atropine, quinine, strychnine, and veratrine (the latter in high concentrations) were shown to have a curarelike effect, that is, these alkaloids abolish the effect of indirect stimulation on striated muscle in concentrations that do not abolish the effect of direct stimulation.^{20, 21} d-Tubocurarine, atropine, amphetamine, codeine, cinchonine, quinine, quinidine, strychnine, and veratrine had a curarelike effect (as shown in the present experiments) in that they decreased the acetylcholine sensitivity of the rectus abdominis muscle in relatively low concentrations but did not decrease the potassium sensitivity in the same concentrations.

SUMMARY

1. The effect of eighteen alkaloids on the acetylcholine and potassium sensitivity of striated muscle were investigated.

2. The acetylcholine sensitivity was increased by physostigmine, ephedrine, epinephrine, ergotamine, pilocarpine, morphine, and yohimbine (the latter three in higher concentrations), and was decreased by the other alkaloids tested.

3. The potassium sensitivity was increased in the presence of all alkaloids tested (except epinephrine and cocaine), and was decreased by epinephrine and cocaine, and, in higher concentrations, by d-tubocurarine, strychnine, quinine, quinidine, and atropine.

4. d-Tubocurarine, codeine, atropine, amphetamine, cinchonine, quinidine, quinine, strychnine, and veratrine showed a curarelike effect in that they induced a decrease of acetylcholine sensitivity in low concentrations and such concentrations did not modify the potassium sensitivity of the muscle.

The authors wish to express their gratitude to Smith, Kline, & French Laboratories, Philadelphia, Pa., for the generous supply of amphetamine; to Sandoz Chemical Works, Inc., New York, N. Y., for the ergotamine; to E. R. Squibb & Sons, New York, N. Y., for the d-tubocurarine; and to S. B. Penick and Co., New York, N. Y., for the veratrine.

LABORATORY METHODS

DILUTION TECHNIQUE FOR RAPID ESTIMATION OF DIHYDROSTREPTOMYCIN AND OTHER ANTIBACTERIAL AGENTS IN BODY FLUIDS

S. F. QUAN AND V. KREEKIS
SAN FRANCISCO, CALIF.

THE technique to be described is a simple dilution procedure for the rapid estimation of dihydrostreptomycin,^{*,1} streptomycin, penicillin, or other antibacterial agents in a fluid medium. Theoretically, dihydrostreptomycin should be readily assayed by many of the rapid methods used for the determination of streptomycin, but some chemical methods²⁻⁴ are no longer applicable due to modification^{1, 5} of the structure. The microbiologic, nephelometric methods^{1, 6, 7} are generally impossible to apply to blood, and agar plates⁸⁻¹⁰ are laborious and cumbersome when used for infrequent samples. A simple dilution method for rapid estimation of antibiotics in the blood is a clinical and research necessity. Such a technique was not found in the literature.

The following procedure, which has been used successfully for over two years for the determination of streptomycin,¹¹ is based on the profuse growth of a large inoculum of a sensitive test organism and on its ability to reduce a solution of methylene blue added after growth has begun. The reaction produces a clear, easily read end point. The tubes in which growth has occurred are easily distinguished from those in which it has been inhibited by the antibacterial agent; in the latter, the blue color remains unchanged. While the end point can be determined in three hours and the concentration of the antibiotic can be estimated then, a sharper end point is obtained after four hours.

METHOD

The following method is used for the determination of an unknown concentration of dihydrostreptomycin (or streptomycin) in a blood sample, whether whole blood, plasma, or serum. The test organism employed is a strain of *Bacillus prodigiosus* (*Serratia marcescens*) which reduces methylene blue in the presence of 0.3 unit, but not 0.4 unit, of dihydrostreptomycin per cubic centimeter of 1 per cent peptone in physiologic saline solution. Streptomycin in a concentration of 0.4 μ g also inhibits reduction, while a concentration of 0.3 μ g per cubic centimeter is not inhibitory.

Procedure (Blood, Plasma, or Serum).—To the first tube of a series of ten sterile small test tubes (13 by 100 mm. or 13 by 150 mm.), each containing 1.0 c.c. of physiologic saline

From the George Williams Hooper Foundation for Medical Research, University of California.

This work, recommended by the Committee on Medical Research, was done under a contract between the Office of Scientific Research and Development and the University of California.

Received for publication, July 19, 1947.

*Obtained through the courtesy of Dr. Fred Stimpert, Parke, Davis & Co., Detroit, Mich.

solution, is added 1.0 c.c. of the blood (citrated or heparinated) to be assayed for dihydrostreptomycin. With a fresh pipette the blood and saline solution are mixed in the first tube and 1.0 c.c. is transferred to the second tube; another fresh pipette is used to mix and transfer 1.0 c.c. to the third tube, and so on; 1.0 c.c. is discarded from the tenth tube, the last of the series.

A control series is set up in an identical manner, using instead of the unknown blood sample defibrinated sheep or rabbit blood or, preferably, horse serum containing 100 units of dihydrostreptomycin per cubic centimeter. To each of the ten tubes in both the unknown and the control series is added 1.0 c.c. of 10^{-2} dilution of a heavy (sixteen to twenty-four hours' growth at $37^{\circ}\text{C}.$) culture of *B. prodigiosus* in physiologic saline solution containing 1.0 per cent peptone. Shake the tubes and incubate at $37^{\circ}\text{C}.$ for two hours. Then add to each tube 0.2 c.c. of a 1:10,000 solution of methylene blue dissolved in physiologic saline solution. After shaking to obtain an evenly colored mixture, each tube is layered with 0.5 c.c. of mineral oil (liquid petrolatum, U.S.P.). The tubes are then incubated again at $37^{\circ}\text{C}.$ for another two hours.

To estimate the concentration of dihydrostreptomycin in the unknown blood sample, the number of tubes in the unknown series in which the blue color is unchanged is compared with the number in the control series. Thus, if six tubes in the control series remained blue and the unknown series showed five blue tubes, the latter would contain 50 units; if six tubes in the unknown remained blue, it would contain 100 units, or equal the control; seven blue tubes in the unknown series would indicate a concentration of 200 units, and so forth.

Procedure (Urine or Aqueous Fecal Extract).—The same procedure is used for urine and fecal extracts containing antibiotics. Sixteen to twenty-four hour cultures of *Escherichia coli*, Waksman and associates^{11, 12} grown at $37^{\circ}\text{C}.$ in 1 per cent peptone, have been used in 10^{-3} dilutions for the determination of dihydrostreptomycin or streptomycin in such samples. This coliform organism does not produce reduction when dihydrostreptomycin is present in 1.1 units per cubic centimeter or streptomycin in $1.0\text{ }\mu\text{g}$ per cubic centimeter, but is effective in 1.0 unit of dihydrostreptomycin or $0.9\text{ }\mu\text{g}$ of streptomycin per cubic centimeter. However, a 10^{-2} dilution of *B. prodigiosus*, which grows more slowly than *Esch. coli*, is preferable.

The high levels of streptomycin present in urinary or fecal samples taken during therapy necessitate a tenfold dilution of the original sample, and the final value for the unknown sample is obtained by multiplying the estimate by ten.

DISCUSSION

Sterile glassware is used entirely, but plugs for the test tubes are not necessary. The methylene blue solution and the mineral oil are not sterile. The test may be read one hour after the addition of methylene blue solution and mineral oil, or at any time thereafter. However, reading two to four hours following the second period of incubation is recommended. The number of tubes reduced varies directly with the time of incubation. A late reading not only gives lower sensitivity, but may also render the test inaccurate by allowing contaminants to grow. The latter has not yet been encountered in this laboratory, where no special precautions are observed, and readings at the end of twenty-four hours have been found to be in good agreement with those made earlier, except when the antibiotic was present in low concentration.

In the presence of a 10 per cent or more concentration of blood, for example, in the first and second tubes of the blood dilution series, reduction of methylene blue is not a reliable index of growth manifestations, and non-reduced methylene blue does not necessarily indicate inhibition. The cause of this anomaly is unknown. It is necessary at present to avoid testing whole

blood samples which will give end point results in the initial tubes. Serum and plasma do not react in this way. The testing of serum in place of blood has still other advantages: blood may conveniently be allowed to clot, and serial dilutions may be made without changing pipettes from tube to tube. Under the conditions described, the varying amounts of serum in successive tubes have no noticeable influence on the growth of *B. prodigiosus*.

While sterilization of fresh urine samples is not absolutely necessary, it is recommended that 5 c.c. be heated for twenty to thirty minutes in boiling water before use in antibiotic determination. Dihydrostreptomycin solutions may be sterilized by steam autoclaving for thirty minutes at 115° C. and 15 to 20 pounds of pressure without loss of potency. Solutions of streptomycin, penicillin, or tyrothricin should not be subjected to either treatment. Dilutions of fecal extracts may be tested by the same procedure used for urine.

APPLICATION

These procedures, which are capable of wide application, can be used with any sensitive organism which grows rapidly under the described conditions. In this laboratory, the aforementioned organisms and *Bacillus subtilis*, *Salmonella typhimurium*, *Staphylococcus aureus* SM, *Staphylococcus aureus* 209P, and *Streptococcus haemolyticus* N.Y.5 have been successfully used in the assay of penicillins, streptothricin, tyrothricin, alkyl quaternary ammonium salts, and some aromatic amidines.

Test data are given in Table I. Values obtained by other methods are included^{7, 8, 13-15} for purposes of comparison.

SUMMARY

A simple microbiologic serial dilution technique has been presented in detail for the four-hour estimation of dihydrostreptomycin or streptomycin in whole blood, plasma, serum, urine, or fecal extractions.

The procedure has also been applied to other antibacterial agents, such as penicillins, streptothricin, tyrothricin, quaternary ammonium salts, and aromatic amidines.

ESTIMATION OF URIC ACID IN SERUM AND WHOLE BLOOD BY AN ELECTROPHOTOMETRIC MODIFICATION OF FOLIN'S METHOD

E. H. BENSLEY, M.D., SALLIE MITCHELL, B.Sc., AND PHYLLIS WOOD, B.Sc.
MONTREAL, CANADA

THE purpose of this communication is to report a study of the estimation of uric acid in serum and in whole blood by an electrophotometric modification of Folin's direct macromethod.^{1,2} Details of the adaptation of Folin's technique to the electrophotometer, recoveries of uric acid from serum and whole blood, and estimations of the uric acid content of serum and whole blood of normal subjects are presented.

This investigation was stimulated by a report by Jacobson³ of the satisfactory results of the application to serum of Folin's direct method of estimation of blood uric acid.⁴ In thirty experiments, in which uric acid was added to serum (or plasma), the average recovery was 90 per cent and individual recoveries were 80 per cent or higher in all but one instance. The upper limit of the normal range of serum uric acid concentration was 6.0 mg. per cent, and values above this were found in 174 of 177 tests on twenty-one patients with gout. These recoveries and the demonstration of this high incidence of hyperuricemia in gout are in contrast with the findings of many investigators. Thus, in 1941, Bulger and Johns⁵ stated that the uncertainty regarding the reliability of methods of estimation of blood uric acid was so great that some laboratories no longer attempted these tests. We were therefore prompted to study Folin's method with special reference to its application to serum and, since whole blood is commonly used for estimation of uric acid, to compare results obtained with serum and whole blood.⁶

Electrophotometric Modification of Folin's Direct Macromethod.—Preliminary experiments with Folin's technique showed that the color of the blank was not constant. At times it was pale to moderately deep yellow; at other times, although pale yellow at first, it rapidly became pale green. These variations appeared to be due to impurities in the sodium cyanide used in the urea-cyanide reagent[†] and, to a less extent, to very small changes in the proportions of sodium tungstate and phosphoric acid in the uric acid reagent.³ A change in the blank occurred whenever a new lot of sodium cyanide was used and sometimes when a new uric acid reagent was prepared. It was therefore decided to adapt the technique to the electrophotometer, since this would permit a correction for the blank with each estimation.

From the Department of Metabolism and Toxicology, the Montreal General Hospital.
This work was done with the aid of a grant from Mr. T. Howard Stewart, a Governor of this Hospital.

Received for publication, Aug. 4, 1947.

*In all tests with whole blood the anticoagulant was sodium oxalate and red cells were laked before precipitation of proteins.⁶ Unlaked blood filtrates⁷ were not used since they yield values which are influenced by a variable degree of extraction of chromogenic material from the red cells.⁴

†Folin² recommended the use of Merck's reagent sodium cyanide. In our experience this does not ensure constancy of the blank.

A Fisher electrophotometer with two photoelectric cells, null adjustment, microabsorption cells and a filter of maximum transmission at 525 m μ was used.

Experiments with aqueous solutions of uric acid showed concentration to be directly proportional to the negative logarithm of the transmission factor with amounts of uric acid below 0.6 mg. per cent only (equivalent to a serum or blood uric acid of 6 mg. per cent). The rate of color development was variable and appeared to be markedly influenced by impurities in the sodium cyanide used in the urea-cyanide reagent. With some lots of cyanide color development was slow and a deep blue color was not formed until thirty to forty minutes after addition of uric acid reagent. With other lots color development was more rapid, the blue color was deep at the end of twenty minutes and was replaced by a green color between thirty and forty minutes. A calibration curve could not be used and a standard, equivalent to a blood uric acid of 4 mg. per cent, was set up with each unknown as described by Folin.^{1, 3}

Experiments with Folin-Wu filtrates representing 1 in 10 dilutions of serum and blood^{3, 6} showed their behavior to be similar to that of aqueous solutions. Rate of color development was variable but paralleled that of the standard set up at the same time with the same reagents.

On the basis of these findings, Folin's direct macromethod was adapted to the electrophotometer as follows. A standard, equivalent to a blood uric acid of 4 mg. per cent, and a blank were set up with each unknown. Readings were made at any time between twenty and forty minutes after addition of uric acid reagent. With the blank in position in the electrophotometer, the galvanometer was adjusted to read zero on the logarithmic scale. Readings of the standard and the unknown were then made. Since the colors of the blank, the standard, and the unknown were not stable, readings were made in as rapid succession as possible. The concentration of uric acid in the unknown was calculated from the readings of the logarithmic scale of the galvanometer. If the value obtained was higher than 6 mg. per cent, the test was repeated with a filtrate diluted with water to obtain a final reading in the range of direct proportionality between concentration and logarithmic scale readings.

The modifications introduced in adapting the technique to the electrophotometer only have been described; otherwise the preparation of reagents and procedure of the test were as described by Folin.¹⁻³

Recovery of Uric Acid From Serum and Whole Blood.—Uric acid was added to serum and whole blood in concentrations ranging between 2 and 10 mg. per cent. Filtrates, representing dilutions of serum or blood of 1 in 10, were prepared by the Folin-Wu procedure^{3, 6} and estimations before and after addition of uric acid were made by the electrophotometric modification of Folin's direct macromethod. The results (Table I) show that recoveries from whole blood were lower and more variable than those from serum. Demonstration of the inaccuracies involved in analysis of the uric acid content of whole blood is not new and the factors responsible for poor recoveries have been discussed

in the literature.^{1, 2, 3} The figures reported here are of interest in providing a comparison between recoveries from serum and whole blood by the same technique.

TABLE I. RECOVERIES OF URIC ACID FROM SERUM AND WHOLE BLOOD

	TOTAL NUMBER OF EXPERIMENTS	RECOVERY OF ADDED URIC ACID ^a			NUMBER OF EXPERIMENTS WITH RECOVERIES OF 85% OR MORE
		MAXIMUM	MINIMUM	AVERAGE	
Serum	30	110%	78%	94%	29
Whole blood	30	105%	55%	83%	15

^aRecoveries were calculated by the formula $\frac{U_2 - U_1}{a} \times 100\%$, in which U_1 and U_2 were amounts of uric acid found before and after addition of uric acid, respectively, and a was the amount added. In some publications recovery is calculated as $\frac{U_2}{U_1 + a} \times 100\%$. The latter method yields higher figures, the discrepancy is especially marked when U_1 is high and a is low.

Variations in the color of the blank and in the rates of color development by standards and unknowns had no influence on recoveries. It should be noted here that these recovery experiments were not done with only one set of reagents. Six lots of sodium cyanide, representing products of three manufacturers, and four preparations of uric acid reagent were used.

These results indicate that serum is to be preferred to whole blood for estimation of uric acid by Folin's method.

Normal Values of Uric Acid Content of Serum and Whole Blood.—Blood was collected from 100 normal individuals with no family history of gout. There were 63 men and 37 women. The maximum, minimum, and average ages were 58, 15, and 29 years respectively. Samples were obtained in the morning one to three hours after breakfast and were not collected under oil.⁴ The latter precaution was omitted since it is inconvenient in routine work and we wished to determine normal values with samples collected under the usual conditions of exposure to air. Uric acid in Folin-Wu filtrates of serum and whole blood was estimated by the electrophotometric modification of Folin's direct macro-method.

The results are shown in Tables II and III. As expected from the recoveries, average values obtained with whole blood were lower than those obtained with serum. Individual values showed considerable variation. Thus, whole blood values were equal to or higher than serum values in 15 of the 100 tests

*The ratios of the difference between the means to the probable error of the difference show the differences between whole blood and serum values to be statistically significant. Statistical formulas used

$$\sigma \text{ sample} = \sqrt{\frac{\sum v^2}{n}}$$

$$P. D. \text{ sample} = 0.6745 \times \sigma \text{ sample}$$

$$\sigma \text{ mean} = \frac{\sigma \text{ sample}}{\sqrt{n}}$$

$$P. D. \text{ mean} = 0.6745 \times \sigma \text{ mean}$$

$$\sigma(M_1 - M_2) = \sqrt{(\sigma M_1)^2 + (\sigma M_2)^2}$$

$$P. D. (M_1 - M_2) = 0.6745 \times \sigma(M_1 - M_2)$$

In these formulas, σ , standard deviation, v , individual deviation from mean, n , number of measurements, $P. D.$, probable error, M_1 and M_2 , means of two series of measurements.

and, among the remaining 85, differences between serum and whole blood values varied between 0.1 and 2.9 mg. per cent. In individual cases, the uric acid content of serum cannot be predicted from the value obtained using whole blood.

TABLE II. SERUM URIC ACID IN ONE HUNDRED NORMAL SUBJECTS

	NUMBER OF TESTS	SERUM URIC ACID (MG. PER CENT)				
		MAXIMUM	MINIMUM	AVERAGE	PROBABLE ERROR SAMPLE	PROBABLE ERROR MEAN
All cases	100	6.9	2.9	4.5	± 0.6	± 0.06
Men	63	6.9	2.9	4.8	± 0.6	± 0.08
Women	37	5.7	2.9	4.0	± 0.4	± 0.07

Our normal values of serum uric acid are slightly higher than those reported by Jacobson.⁴ This is probably explained by the fact that our samples of blood were not protected from exposure to air, whereas Jacobson collected blood under oil. This investigator has shown that exposure of blood to air may increase the apparent uric acid content of serum by as much as 0.6 mg. per cent. It should also be noted that Jacobson's tests were done while the subject was in the fasting state, whereas those reported here were done one to three hours after breakfast. However, there was no evidence that our highest values were related to consumption of breakfasts of high purine contents.

TABLE III. WHOLE BLOOD URIC ACID IN ONE HUNDRED NORMAL SUBJECTS

	NUMBER OF TESTS	WHOLE BLOOD URIC ACID (MG. PER CENT)				
		MAXIMUM	MINIMUM	AVERAGE	PROBABLE ERROR SAMPLE	PROBABLE ERROR MEAN
All cases	100	6.4	2.2	3.8	± 0.6	± 0.06
Men	63	6.4	2.5	4.1	± 0.6	± 0.08
Women	37	4.4	2.2	3.2	± 0.4	± 0.07

Nothing would be gained from a detailed comparison of our data with those obtained by other techniques^{5, 9-12} since values depend to a considerable extent on the technique employed. In general, values obtained with serum or plasma are higher than those obtained with whole blood and indicate the upper limit of the normal range for serum or plasma to be 6 to 7 mg. per cent.¹⁴

As shown in Tables II and III our data agree with those reported elsewhere^{5, 10, 12} in demonstrating lower values in women than in men.²

SUMMARY

1. An electrophotometric modification of Folin's direct macromethod of estimation of uric acid in blood is described. This was developed to eliminate errors due to variable blanks met with in this technique.

2. With this method recoveries of uric acid from serum were higher and less variable than those from whole blood. Serum is therefore to be preferred to whole blood for estimation of uric acid by this technique.

*The ratios of the difference between the means to the probable error of the difference show these differences between men and women to be statistically significant.

3. Estimations of the uric acid content of whole blood and serum were made in 100 normal individuals with no family history of gout. The average values obtained with whole blood were significantly lower than those obtained with serum, but individual values showed considerable variation. In individual cases the uric acid content of serum cannot be predicted from analysis of whole blood.

The normal range of concentration of uric acid in serum was 2.9 to 6.9 mg. per cent.

Whole blood and serum uric acid concentrations were significantly lower in women than in men.

The authors wish to express their obligations to the Nursing Staff of the Employee Welfare Clinic of the Sun Life Assurance Company of Canada and to Miss Roberta Geldert and Miss Thelma Todd of the Department of Metabolism and Toxicology of the Montreal General Hospital, who collected the blood samples from normal subjects.

A DERMAL PLETHYSMOGRAPH FOR THE RECORDING OF SKIN-WHEALING REACTIONS

CARL C. PFEIFFER, M.D., ELIZABETH H. JENNEY, A.B.,* AND HARRY L. WILLIAMS
CHICAGO, ILL.

PREVIOUS comparative studies on intradermal wheals, initiated shortly after the introduction of the McClure-Aldrich saline wheal disappearance tests,^{1, 2} were disappointing because of lack of quantitative methods for the measurement of wheal volumes. The first effort at quantitation was probably that of Schade³ in 1912 who used a weighted disk placed on top of saline wheals and recorded kymographically the slow sinking and disappearance of these wheals. Alexander and co-workers⁴⁻⁶ traced the irregular wheal boundary with a planimeter and used the recording as an index of wheal size. Gowen⁷ suggested a practical clinical method of approximating the size of wheals by the use of a thin 4 cm. square glass with three circles, 1 cm., 2 cm., and 3 cm. in diameter, marked on its surface. For measurements, the glass square was placed over the wheal with the point of injection in the center of the 1 cm. circle. A rubber stamp with circles of the same size was used to record and transfer a rough outline of the wheal size to the patient's chart.

Intradermal wheals have been used in animals and man to compare the degree of irritation caused by local anesthetics.⁸ An accurate means of wheal measurement would suggest extending this simple test to study the intradermal tissue tolerance of other new drugs. The tendency of many drugs to cause an inflammatory reaction or cellular irritation, as well as the characteristic curve of absorption, might thus be determined by the use of various concentrations of the test substance. The results of intradermal injections could then be correlated with the intramuscular and subcutaneous reactions to the drug. During the course of studies on new local anesthetics a distinct need was felt for a more accurate means of measuring wheals and cutaneous reaction to intradermal injections. Accordingly the following dermal plethysmograph was designed.

APPARATUS

The dermal plethysmograph (Fig. 1) consists of a 20 to 30 cm. glass capillary tube (bore, approximately 1 mm.) opening into a hollowed-out rubber base. Using rubber cement, a thin rubber membrane is cemented to the rubber base of the plethysmograph and the edges of the membrane are then trimmed with scissors. When the tube and rubber base are filled with an 80 per cent alcoholic solution of toluidine or methylene blue, any pressure against the rubber membrane causes the blue solution to rise in the tube.

Received for publication, Aug. 25, 1947.

*Submitted in partial fulfillment of the requirements for the degree of Master of Science in Pharmacology.

When weighted with sufficient lead to make the entire instrument weigh 100 grams it is extremely sensitive to volumetric changes of the skin surface. The pulse is seen as a regular rise and fall of the blue column as the instrument rests on the subject's arm. Greater weight may cause a gradual depression of the supporting skin and a resultant rise of the blue column of fluid over a forty-five minute period. With an external diameter of 37 mm. and an internal opening of 21 mm., the instrument applies 100 grams of weight over

Fig. 1.—Dermal plethysmograph.

an area of 728 sq. mm., or approximately 50 grams per 350 square millimeters. In this regard Schade³ found that 50 grams per 50 sq. mm. did not exceed the elastic limits of the skin when applied for a two-minute period. Control readings indicate that 100 grams per 728 sq. mm. does not exceed the elastic limits when applied for a forty-five minute period, since no spontaneous rise occurs during this time. That changes in skin temperature are not important in the readings of the skin plethysmograph is shown by Fig. 2. The bases of three plethysmographs were immersed to a depth of 2 mm. in a water bath and the temperature was raised slowly from 22 (room temperature) to 37.5° C. Over the temperature range encountered in the skin of the forearm (33 to 37° C.) the readings of the plethysmographs increased only 1 to 2 mm., which

is not sufficient to necessitate a correction. When the capillary is calibrated with mercury it is found that a capillary of approximately 1.0 mm. bore will contain 0.009 c.cm. of water per centimeter length. Thus with individually calibrated capillaries, graph paper may be used to measure the changes in volume of the skin surface. Knowing that the wheal is made in the dermis,^{9, 10}

Fig 2.—The possible effect of skin temperature on the volumetric readings of the dermal plethysmograph. A, B, C, readings in centimeters of three dermal plethysmographs.

one can assume that at least one-half is submerged in the soft subcutaneous tissues so that only the top half of any given wheal could possibly be measured. The instrument is calculated on this basis to be 63 per cent effective. That is, when 0.2 c.c. wheals were made with serum, the total volume measured is 0.063 c.c. rather than the theoretic value of 0.10 cubic centimeter.

PROCEDURE

Most consistent results are obtained with a trained and relaxed subject reclining on a bed with the arm immobilized with small sand bags. A series of control readings are taken on a level area of the flexor surface of the subject's forearm by lifting and replacing the plethysmograph several times. The

average of these control readings is taken as a base reading. Each time before removing the plethysmograph from the skin the stopcock should be closed to prevent bulging of the rubber membrane due to pressure from the column of fluid. It is opened upon replacing. After the control readings have reached a constant value, the instrument is removed from the arm and a wheal is raised in the exact center of the area where the dermal plethysmograph had been resting. The wheal is made by injecting intradermally 0.2 c.c. of the sterile test solution using a $\frac{1}{4}$ c.c. tuberculin syringe and a 27-gauge one-fourth inch needle. The stop watch is started after the needle is inserted and immediately before the solution is injected. The dermal plethysmograph is replaced over the identical area, and readings are taken at thirty and sixty seconds and at every minute thereafter for a period of forty-five minutes.

With the enormous pressures required for whealing,¹¹ some variation in wheal size may result from leakage of a test solution either back around the syringe plunger in a poorly fitting syringe or between the syringe and the needle. To avoid this in quantitative work, each syringe must be carefully tested for leaks by the following procedure: a needle is firmly attached to the syringe, then inserted into a solid rubber stopper; if pressure exerted on the syringe causes the fluid in the syringe to escape at the bevel or back along the piston, the syringe is discarded. Puncturing of the basal layer of the corium (as by poor technique) also causes a smaller and more rapidly disappearing wheal. (Some evidence has been obtained which indicates that a markedly irritating solution may regularly result in smaller wheals.) Finally, the primary factors in the size and disappearance of wheals are the varying abilities of the solutions to spread between the cell walls, to penetrate the tissues and the cell walls, to cause cellular swelling, to increase capillary permeability, and to cause delayed inflammatory reactions.

Since the human subject must lie supine for forty-five minutes we have found it expedient to use three dermal plethysmographs simultaneously and make three wheals in rapid succession in the skin of the subject's forearm. The tabulation of data from three plethysmographs at minute intervals is easily within the skill of a trained operator.

RESULTS

Example I. Reaction to Insect Toxin.—Subject W. F., a 21-year-old man known to have an immediate whealing reaction to mosquito bites, was chosen for this experiment. A single mosquito (*Aedes aegypti*) was allowed to bite the subject in the volar surface of the forearm. After the mosquito had become engorged and had withdrawn his proboscis, the dermal plethysmograph was placed on the site and development of the wheal measured (Fig. 3, A). The experiment, when repeated the next day, produced a similar type of whealing reaction (Fig. 3, B). The response curves are sufficiently analogous to indicate the usefulness of this method of recording when immediate reactions to an injected substance are anticipated.

Example II. Reaction to Histamine Diphosphate.—Two subjects were chosen for this experiment. Subject A, a 20-year-old man, was known to

react quite markedly to intradermal histamine, while Subject B, a 38-year-old man, was known to have a less marked response. Neither subject had an allergic history. The skin of the subject was cleaned with 70 per cent alcohol, and a drop of histamine diphosphate, 1:1,000, was placed on the clean dry skin. A sterile 27-gauge one-fourth inch needle was then used to make two punctures through the dermis beneath the drop of histamine. The excess histamine was blotted off with gauze and the recording instrument was placed over the site. This technique results in a uniform whealing response when used in

Fig. 3.—The response of a normal subject to mosquito bites (*Aedes Egypti*) on two successive days.

experimental subjects during the summer months. (In winter months we have found the skin to be much less responsive.) It is evident from inspection of the curves obtained on three successive days (Fig. 4) in each subject that Subject A has a consistently greater response to the whealing action of histamine than Subject B who has a consistently minimal response. These separate families of curves are distinct and probably reflect the sensitivity of these two subjects when histamine is applied in this manner.

Example III. Disappearance Curves of Saline and Glucose.—Previous examples of the application of the dermal plethysmograph have shown charac-

Fig. 4.—The response of two normal subjects, A and B, to histamine on three successive days.

Fig. 5.—Wheal disappearance times (average of five subjects) when solutions of varying tonicity are injected intradermally.

teristic curves of wheal growth. Wheals of various substances in solutions (such as local anesthetics, irritant drugs, and saline) can be made, the wheal size measured, and a characteristic wheal disappearance curve obtained for each substance. The average disappearance curve of five subjects injected with various saline solutions and glucose is characteristic and predictable (Fig. 5). Clinically we know that 5.5 per cent glucose solution is more irritating than 0.9 per cent NaCl solution. The rising plateau curve obtained with glucose simulates the curves of other irritant substances such as nupercaine 1:500 or diothane 1:500.* Sodium chloride, 0.45 per cent, most closely approximates the saline level of the extracellular fluid and in these experiments disappears most rapidly from an intradermal site. Sodium chloride, 1.8 per cent, has an irritant quality similar to that of glucose.

SUMMARY

A dermal plethysmograph (whealometer) has been constructed which measures with a known degree of accuracy the growth and disappearance rate of dermal wheals. Wheal measurement is suggested as a useful procedure for the study of histamine response or other immediate whealing responses and for the determination of the rate of disappearance of various substances injected intradermally.

PROCEEDINGS OF THE CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twentieth Annual Meeting
Chicago, Ill., Oct. 31 and Nov. 1, 1947

PROGRAM

SCIENTIFIC PROGRAM—OCTOBER 31, 1947

FRIDAY MORNING, 9:15 A.M.

1. EFFECT OF URETHANE ON LEUCEMIA

PAUL L. BEDINGER, M.D. (BY INVITATION), HENRY G. PONCHER, M.D., AND
LOUIS R. LIMARZI, M.D., CHICAGO, ILL.

Recent investigation has shown that urethane (ethyl carbamate) produces a marked drop in the leucocyte count of both human leucemia and mouse myelogenous leucemia. Normal leucocytes appear to be more refractory to urethane than do leucemic cells. In human leucemia following the oral administration of urethane over a period of several months a favorable effect has been reported in the subjective symptoms, lymphadenopathy, hepatosplenomegaly, and the leucocyte blood pattern. The exact action of urethane is not understood, but a mechanism of inhibition of mitosis of immature cells has been suggested.

Seventeen children and adults with acute leucemia, fourteen patients with chronic lymphatic leucemia, four with chronic myeloid leucemia, and one with monocytic leucemia (Schilling type) were treated with urethane. The drug was given orally in simple syrup or as $7\frac{1}{2}$ grain tablets. Because of intolerance in some cases, mainly shown by nausea and vomiting, 5 grain enteric-coated tablets proved satisfactory. The average daily dose of the drug ranged from 1 to 5 Gm. given over a period of two days to six months.

In the patients with acute leucemia little or no benefit was observed from the use of urethane, although a rapid and marked fall in the leucocyte count was noted in all cases. With the exception of one child who showed an apparent temporary remission in the blood and bone marrow pattern without clinical improvement, all the other patients still presented the blood and bone marrow findings of acute leucemia. The severe anemia and thrombopenia necessitated the use of frequent blood transfusions in spite of the drop in leucocyte count during the administration of urethane. Terminal cases of acute leucemia showed a rise in the leucocyte count in spite of the administration of urethane. Eleven of these patients have died and in several of the cases at autopsy the hemopoietic organs, as well as the others, showed a general infiltration of tissues by leucemic cells.

In chronic myeloid leucemia and chronic lymphatic leucemia urethane produces a gradual or rapid fall in the leucocyte count with apparent symptomatic improvement. Enlarged lymph nodes and enlarged spleen decreased in size, but in no case did they disappear. Although a more mature type of blood pattern was observed in the patients with chronic myeloid leucemia following treatment, immature cells of the myeloid series were always present in the

peripheral blood. In the patients with chronic lymphatic leucemia, the fall in the leucocyte count was associated with an improvement in the blood and bone marrow picture, although in no case was a complete hematologic remission induced by the drug. Improvement in the hemoglobin and erythrocyte count was noted in several cases. There is some indication that remissions induced by roentgen treatment may be prolonged by the use of urethane. No clinical or hematologic improvement was noted in the patient with monocytic leucemia.

Urethane produces varying degrees of toxic granulations in the neutrophilic leucocytes which is especially marked in the cases of acute leucemia. Urethane was without effect on the basal metabolic rate and certain blood chemical constituents including uric acid. The tentative conclusions are that (1) in patients with acute leucemia urethane in oral doses of 1 to 5 Gm. daily will produce moderate to marked fall in the leucocyte count during a period of one to several weeks; (2) in patients with chronic lymphatic leucemia and chronic myeloid leucemia there is a tendency for the blood pattern to approach a more mature type with a decrease in the size of the lymph nodes and spleen; (3) the temporary remission induced by the drug in chronic leucemia is never as complete as that following roentgen therapy; (4) there is no indication that urethane has any permanent effect on the leucemic process.

2. VARIATIONS IN BLOOD PLATELETS IN ALLERGIC INDIVIDUALS FOLLOWING THE INGESTION OF TEST FOODS

FREDERICK J. POHLE, M.D., AND EPHRAIM B. COHEN, M.D. (BY INVITATION)
MADISON, WIS.

Purpura as a manifestation of allergy is well known. Such hemorrhagic disorders are usually nonthrombocytopenic, although in rare instances reference has been made to cases of thrombocytopenic purpura presumably due to a food sensitivity. Squier and Madison, particularly, have emphasized the role of food allergy in the etiology of certain cases of thrombocytopenic purpura. The purpose of the present investigation was to quantitate the platelet response in allergic individuals to the ingestion of test foods.

Twenty sets of observations were made on sixteen allergic subjects. Under basal conditions, leucocyte and platelet counts were performed twice at fifteen-minute intervals prior to ingestion of a standard portion of a test food to which the subject was known to be sensitive. The postprandial blood counts were done at fifteen, thirty, sixty, and ninety minutes. Tourniquet tests were done immediately prior to the feeding and were repeated on the opposite arm sixty minutes later. Platelets were enumerated by one of us (F. J. P.) employing a direct method which, in our hands, admits a technical error of approximately ± 4 per cent.

A positive leucopenic index, as evidenced by a postprandial decrease of 10 per cent or more as suggested by Randolph, was demonstrated in seventeen of the twenty studies. On the same basis, a positive "thrombopenic index" was observed fourteen times. The average change in the leucocyte count for the entire group was -22 per cent; the average change in the platelet count was -19 per cent. In fifteen of the twenty sets of observations the subject demonstrated clinical manifestations of sensitivity to the test food. The tourniquet test became positive after the ingestion of the offending food in two individuals. These two patients showed a decrease in platelets of 31 to 33 per cent, respectively. Similar observations of the leucocyte and platelet counts and the tourniquet test were made on a control group of nonallergic individuals, none of whom demonstrated these changes.

These data suggest that this clinical method may aid in the detection of food allergies and that this type of observation may be of value in the study and management of certain thrombopenic states.

3. NEUTRALIZATION OF HEPARIN WITH PROTAMINE (SALMINE)

THOMAS W. PARKIN, M.D. (BY INVITATION), AND WALTER F. KVALE, M.D.
ROCHESTER, MINN.

Hemorrhage due to a prolonged blood coagulation time resulting from the administration of heparin can be controlled only by discontinuing the administration of heparin and by giving blood transfusion. The effects of neither of these procedures may be sufficiently prompt to prevent the hemorrhage from reaching serious proportions.

Certain protamines are known to neutralize heparin in vitro and in animals. Protamines also appear to have certain toxic effects when given to different species of animals. The assumption appears in the literature that on the basis of animal studies protamines cannot be administered safely to human beings. On the contrary, in 1938, Jorpes reported from Sweden that the protamine, elupeine, can be injected intravenously in man to neutralize heparin. In view of the conflicting reports in the literature, further work seemed necessary.

The purpose of this investigation was to determine (1) by work on animals the toxicity of the protamine, salmine, (2) whether salmine can be administered safely to man, and (3) the dosage of salmine required to neutralize the anticoagulant effect of a standard dose of heparin in man.

In vitro studies demonstrated that 1.5 mg. of salmine neutralized 1.0 mg. of heparin, thus showing that there is quantitative neutralization. The lethal dose of salmine in the guinea pig was 6.0 mg. per 100 grams of body weight. Salmine injected intravenously in doses of 90.0 mg. per kilogram in the unanesthetized rabbit and 2.0 mg. per kilogram in the unanesthetized dog produced no reactions. The intravenous injection of salmine in doses of 10.0 mg. per kilogram in the anesthetized rabbit and 2.0 mg. per kilogram in the anesthetized dog produced transient drops in arterial blood pressure. No evidence of anaphylaxis was observed.

Intravenous injections of salmine neutralized heparin which was injected intravenously in dogs. In the dog, elevated coagulation times resulting from the intramuscular injection of heparin in the Pitkin menstruum were temporarily returned to normal levels by single intravenous injections of salmine.

The anticoagulant effect of intravenous injections of heparin in man was studied by determining coagulation times at fifteen- to thirty-minute intervals for a period of three hours. Coagulation times were determined by the Lee-White method with a thermostatically controlled water bath at 37° C. It was found that coagulation times were elevated four times the normal (four minutes) one hour after injection and that then they gradually returned to pre-heparin levels in three hours. With this to serve as a control, 50 mg. of heparin were injected intravenously into ten patients and fifteen minutes later salmine was injected intravenously in doses ranging from 15 to 50 milligrams. In the patients receiving 40 to 50 mg. of salmine, the elevated coagulation times were returned to normal levels within five minutes.

No toxic reactions were noted in any patient during or after the injections of salmine. It is concluded that the intravenous injection of 40 to 50 mg. of salmine promptly neutralizes the anticoagulant effect of 50 mg. of heparin and that such doses of salmine, when given slowly, produce no reactions.

4. SURVIVAL OF TRANSFUSED SICKLE CELLS IN NORMAL SUBJECTS AND OF NORMAL RED BLOOD CELLS IN PATIENTS WITH SICKLE CELL ANEMIA

SHEILA T. E. CALLENDER, M.D.,* AND JAMES F. NICKEL, A.B., ST. LOUIS, MO.
(INTRODUCED BY CARL V. MOORE, M.D.)

This report describes observations made on (1) the survival of normal red blood cells transfused into patients with sickle cell anemia, (2) the survival of red blood cells from patients with sickle cell anemia transfused into normal subjects, and (3) the survival of red blood cells from persons with the sickle cell trait transfused into normal subjects. The Ashby technique of differential agglutination was used. By this method, the time of survival of normal cells in normal recipients has been found to be about 120 days; roughly one-half of the transfused cells disappear within 60 days. Results obtained confirm evidence indicating that the abnormality in sickle cell anemia is an inherent defect in the red blood cells and demonstrate a difference in behavior of erythrocytes from patients with sickle cell anemia and the sickle cell trait.

Normal red blood cells were transfused into three patients with sickle cell anemia. In all three, the survival of the donor cells was similar to that found in normal subjects. This suggests that there is neither a humoral factor in sickle cell anemia nor any element of increased phagocytosis which would accelerate destruction of normal cells.

Four reverse experiments were made using donors with sickle cell anemia and normal recipient subjects. The transfused cells disappeared rapidly from the circulation; nearly all donor erythrocytes were destroyed within thirty days. In one observation, one patient with sickle cell anemia served as a donor and another as the recipient; the transfused cells showed a comparable rapid destruction. A crude measure of the survival of sickle cells in the normal recipients was also made by study of sealed, moist preparations of capillary blood. Sickled donor cells could readily be demonstrated for only about three weeks after transfusion.

Blood from four healthy donors with the sickle cell trait was also given to normal subjects or to patients with mild hypochromic anemia. The survival of these cells was distinctly longer than that from donors with true sickle cell anemia. Four weeks after transfusion, at a time when cells from sickle cell anemia had largely disappeared from the normal recipients' circulation, more than one-half of the sickle cell trait erythrocytes were still circulating. Since these observations are currently in progress, the final survival rates cannot now be given.

The results obtained in this study confirm the evidence that there is an inherent defect in the erythrocytes of patients with sickle cell anemia which is responsible for the accelerated red cell destruction found in that disease. They also demonstrate that cells from subjects with the sickle cell trait have a longer survival time than cells from subjects with sickle cell anemia when transfused into normal recipient subjects. Whether this difference in behavior between sickle cell anemia and sickle cell trait cells is related to the ease with which sickling occurs or to some other qualitative difference in the erythrocytes has not yet been discovered.

*Rockefeller Fellow from the Nuffield Department of Medicine, Oxford, Eng.

5. EFFECT OF EXTRINSIC FACTOR, LIVER EXTRACT, AND FOLIC ACID ON INDUCED MACROCYTIC ANEMIA OF SWINE

ROBERT W. HEINLE, M.D., ARNOLD D. WELCH, M.D. (BY INVITATION),
WALTER L. GEORGE, M.D. (BY INVITATION), MARTIN EPSTEIN, M.D.
(BY INVITATION), AND JACK A. PRITCHARD, M.D. (BY INVITATION)
CLEVELAND, OHIO

Production of macrocytic anemia in a pig by administration of a folic acid-deficient diet with added crude folic acid antagonist has been described by Welch, Heinle, and colleagues. Subsequent studies show the anemia to be associated with megaloblastic hyperplasia of the marrow.

In a previous report such an animal was shown to obtain a hematologic as well as very evident clinical response following the administration of a source of extrinsic factor together with normal human gastric juice. The use of the latter was probably unnecessary, as demonstrated by later experiments. These animals do not develop histamine-fast achlorhydria.

Following the described response, the same pig was allowed to relapse and was given a single injection of 15 units of purified liver extract. This was followed by another hematologic and clinical response.

Another pig with induced anemia received four daily intramuscular injections of 10 mg. of folic acid. This was followed by rapid and marked hematologic and clinical improvement.

A third pig developed severe anemia and neutropenia and became critically ill, appearing to be in a moribund state. Administration of two intramuscular injections of 15 units of purified liver extract, 10 mg. of folic acid, and 35 mg. of niacinamide caused rapid and marked hematologic and clinical improvement.

Bethell and co-workers and Welch and co-workers have offered evidence that a substance (s) in purified liver extract may contribute to the proper utilization of conjugates of folic acid by patients with pernicious anemia in relapse. Results obtained in pigs, however, indicate that extrinsic factor and purified liver extracts are effective even though folic acid is not available to the animal.

Folic acid and its conjugates are not in themselves extrinsic factor as evidenced by the facts that folic acid is effective in pernicious anemia without added intrinsic factor and, further, materials free of demonstrable folic acid or its conjugates may be potent sources of extrinsic factor.

It has been demonstrated by several investigators that purified liver extracts effective in pernicious anemia are devoid of significant amounts of folic acid.

In view of recent experimental data, Welch has proposed that folic acid and the antipernicious anemia principle of liver may function via unrelated chemical pathways. While one is reluctant to believe that these substances have no direct or sequential relationship, it can be stated that data available at this time fail to support the idea of such relationship.

6. FURTHER STUDIES OF THE HYPERSPLENIC MECHANISM IN HUMAN DISEASE SYNDROMES

CHARLES A. DOAN, M.D., AND CLAUDE-STARR WRIGHT, M.D.
COLUMBUS, OHIO

Hypersplenic syndromes may present as acute surgical emergencies or as chronic invalidism and may involve the red cells, and/or neutrophils, and/or thrombocytes. They may reflect pathology inherent and primary in the spleen or secondary to some generalized systemic disease. Splenectomy is the only satisfactory treatment to date.

Diagnosis is dependent upon (1) an adequate history and supporting physical findings (with or without gross splenic enlargement); (2) peripheral cytopenia; (3) sternal marrow aspiration showing normal maturation with compensatory cellular hyperplasia of all deficient circulating elements; (4) an adrenalin test "biopsy" to reveal splenic hypersequestration of all involved cell strains.

The *mechanism* resulting in more or less profound peripheral cytopenia probably reflects both cellular and humoral factors: Parenchymal cellular hypersequestration + excessive concentrations of lysolecithin (or some similar lytic enzyme or enzymes) + R-E cell hyperplasia and hyperphagocytosis = hemolytic anemia, neutropenia, and/or thrombocytopenia. That the hyperplastic bone marrow is actually, as well as apparently, functionally effective in its delivery of essential elements may be seen (1) by immediate direct studies of living marrow cell preparations and (2) by studies at the operating table of splenic artery and vein blood before and after adrenalin induced contraction of this organ. As many as 350,000 platelets have been discovered entering the spleen with only 17,000 leaving it, whereas upon adrenalin introduction via the splenic artery the splenic vein and peripheral capillaries promptly show numbers of platelets leaving the spleen comparable to those carried by the artery. Furthermore, supravital scrapings of the freshly removed spleen show direct microscopic evidence of excessive R-E cell hyperplasia and hyperphagocytosis. In nine pathologic spleens removed for hypersplenism a quantitative increase of lecithinase activity was demonstrated by Scheff and Awny in our laboratory in sharp contrast with two normal control spleens.

Certain clinical and hematologic *recurrences* of hypersplenism may be caused by overlooked accessory splenic tissue, or by its subsequent hypertrophy, or by accidentally implanted "splenosis" fragments. Usually the original hematologic syndrome is repeated, but not necessarily. In one of our series of 216 patients diagnosed on the basis of a hypersplenic mechanism the original problem was that of hemolytic anemia. Splenectomy promptly and permanently alleviated this acute critical danger. Eighteen months later a thrombocytopenic crisis developed and surgical re-exploration, after an appropriate diagnostic study, revealed a 5 gram accessory spleen (extraperitoneal in location at the lower pole of the left kidney), the removal of which completely, and promptly, and permanently restored the platelet equilibrium to normal with cessation of all purpuric manifestations. Recurrences have also been found on surgical re-exploration to be due to a generalized R-E cell hyperplasia and hyperphagocytosis involving liver, lymph nodes, and bone marrow, in which case symptomatic therapy only is available.

The pathologic tissue *classification* recognized in our series of patients covering the past seventeen years, as studied by von Haam and Awny, are:

PRIMARY			
Congenital hemolytic icterus	72	Recurrences	
Thrombocytopenic purpura	62	Accessory spleens	3
Splenic neutropenia	11	Generalized R-E cell hyper-	3
Splenic panhematopenia	10	phagocytosis	
SECONDARY			
(1) Congestive splenomegaly		(4) Inflammatory splenomegalies	
Banti's syndrome	36	Tuberculosis	1
Felty's syndrome	3	Syphilis	1
Acquired hemolytic icterus	6	Monilliasis	1
(2) Infiltrative splenomegaly		Boeck's sarcoid	1
Gaucher's disease	3	Hodgkin's syndrome	3
Xanthomatosis	1	(5) Neoplastic splenomegaly	
(3) Hemoblastic splenomegaly		Retothelio sarcoma	1
Lymphatic leukemia	1	Hemangioma	2
Myelogenous leukemia	1		

The *hypersplenic mechanism*, as now conceived, is an adequate explanation for a rather wide range of human clinical and hematologic syndromes, hitherto considered to be distinct and sharply separated etiologic entities.

7. THE PRESIDENT'S ADDRESS

8. PROGRESS REPORT ON A STUDY OF VASCULAR CHANGES IN THE SKIN IN PREGNANCY

WILLIAM B. BEAN, M.D., MORRIS W. DEXTER, M.D. (BY INVITATION), ROBERT C. COGSWELL, M.D. (BY INVITATION), AND JAMES EMBICK, M.D. (BY INVITATION), CINCINNATI, OHIO

As a continuation of investigations on vascular spiders and palmar erythema in chronic disease of the liver, we have observed similar phenomena in 1,200 pregnant women, 278 of whom have been followed during pregnancy and for at least six weeks after delivery. In the smaller group observed during and after pregnancy there were 207 Negro women and 71 white women. Vascular spiders have been found in 60 per cent of the white women and only 15 per cent of the Negroes, while palmar erythema was found more frequently (49 per cent) in white than in Negro women (31 per cent). These signs tend to appear during the first two trimesters of pregnancy but may originate during the last months of pregnancy. In a control group of nonpregnant women vascular spiders were found in 16 per cent of the white women and none of the Negro women, while palmar erythema was noted in 5 per cent of the white and 4 per cent of the Negro women.

Both vascular spiders and palmar erythema tend to fade at the time of delivery and in approximately 80 per cent of the cases the lesions can no longer be detected six weeks after delivery. We have found no significant difference in disappearance rate between white and Negro women. Analysis of age, season, parity, sex and viability of child, toxemia, and other factors has revealed no special relation to the incidence of vascular changes in the skin. Liver function tests during and after pregnancy have not been significantly different in those with vascular spiders, palmar erythema, or both, and those without the lesions. Studies of the excretion of steroid hormones is in progress, but data are not yet adequate for evaluation.

9. HEREDITARY HEMORRHAGIC TELANGIECTASIA IN ASSOCIATION WITH CEREBRAL MANIFESTATIONS AND PULMONARY ARTERIOVENOUS ANEURYSM

CHARLES F. WILLIAMS, M.D. (By INVITATION), ST. PAUL, MINN., AND
EDMUND B. FLINK, M.D., MINNEAPOLIS, MINN.

Within the last year two cases of hereditary hemorrhagic telangiectasia or Osler's disease were encountered on the medical service of the Aneker Hospital. Both patients presented findings which satisfy the diagnostic criteria of Osler's disease. Both had a family history of repeated epistaxis in several members and in two generations. Both had small spiderlike angiomas on the face and neck and some punctate angiomas on the skin and mucosa of the mouth and nose which bled with arterial spurting. The first patient was anemic at death undoubtedly from chronic blood loss. The second patient had cyanosis and mild polycythemia because of a pulmonary arteriovenous aneurysm. The first patient, who was mentally deficient, had been observed from the age of 32 years at the Aneker Hospital. He had never had hypertension. At the age of 37 years he had an episode of hemiplegia, after which he continued to have fainting spells and hemiparesis. At the age of 46 years he was hospitalized because of sudden temporary loss of consciousness. Eight days later he became comatose and died in twenty-four hours. No autopsy was obtained, but it is probable from clinical evidence that he had suffered an intracerebral or subarachnoid hemorrhage. The second patient had also been admitted to the Aneker Hospital at the age of 30 years because of convulsions and unconsciousness. A diagnosis of idiopathic epilepsy was made. He had no more convulsions until the age of 33, at which time he was hospitalized because of a scalp injury sustained during a convulsion. On auscultation of the chest one could hear a systolic murmur in the second left interspace anteriorly. The murmur was accentuated by inspiration. Fluoroscopy revealed a pulsating mass in the left upper lobe. This mass expanded on deep inspiration and contracted noticeably on the Valsalva maneuver. The effects of respiration and the Valsalva maneuver were recorded by planograms. An electroencephalogram was interpreted as being in keeping with an ordinary epilepsy and was not focal in type. Goldstein has reported a case similar to the first patient. Of the fourteen patients with pulmonary arteriovenous aneurysms reported on, eight seem to have had Osler's disease also, but only one was reported as such. Patients with pulmonary arteriovenous aneurysm reported on have had epilepsy, vertigo, syncope, and attacks of numbness and paresthesias of unexplained variety.

Summary.—Two cases of Osler's disease are presented. Both of the patients had cerebral manifestations and one of them also had a pulmonary arteriovenous aneurysm.

10. FACTORS INFLUENCING PRESSURE IN THE PORTAL VEIN AS MEASURED IN THE INTACT ANIMAL

F. W. HOFFBAUER, M.D., J. L. BOLLMAN, M.D., AND J. H. GRINDLAY, M.D.
(By INVITATION), ROCHESTER, MINN.

The influence of various physiologic factors upon the pressure in the portal vein has been studied in the intact nonanesthetized dog. In the past, most determinations of portal vein pressures have been limited to measurements made in the anesthetized animal during operation. Information as to the effect of exercise, of ingestion of food, and of straining has not been available. A knowl-

edge of such influences may have clinical significance in relation to the problem of portal hypertension. The problems presented by the existence of such collateral venous channels as the gastric and esophageal varicosities in cirrhosis may, in some cases, outweigh the problem presented by the hepatic metabolic alterations.

METHOD

A 24-inch length of flexible polyvinyl chloride plastic tube* of small bore (internal diameter, 2 mm.) is inserted into a branch of the splenic vein at operation. Before the tube is tied in place, it is threaded down the splenic vein until the tip is just within the portal vein. The tube is led to the outside through a stab wound. In order to record changes in intraperitoneal pressure, a thin rubber balloon (capacity, 60 ml.) is placed in the peritoneal cavity. The balloon is filled with water and connected to a similar length of plastic tubing. Pressure in the inferior vena cava has also been determined by a technique similar to that used for the portal vein. A left nephrectomy is performed. A plastic tube is inserted through the renal vein.

The venous cannulae are filled with a citrate solution and the free ends are plugged when readings are not being made. This plastic tubing causes much less reaction in the lumen of the vein than does rubber or glass. Thrombus formation may be delayed by the administration of dicumarol. A free flow of blood from the tube may be obtained for ten to fourteen days, occasionally longer. The time interval is sufficient for complete recovery from the effects of the operation before observations are undertaken. Pressure readings are made in water manometers attached to the side of the dog by means of a light harness. All readings are made with the animal in the standing position.

RESULTS

In normal intact dogs the pressure in the portal vein varies from 4 to 10 cm. of water. The pressure in the inferior vena cava is 0, or occasionally 2 cm. below atmospheric pressure. Exercise produces no significant increase in portal pressure. The straining that accompanies urination, defecation, and vomiting produces sharp increases in the portal pressure. This is associated with increases in intra-abdominal pressure and in inferior vena caval pressure as well.

The ingestion of food produces an increase in portal vein pressure that persists for several hours. Initially this is associated with a rise in intra-abdominal pressure. The latter returns to the original level before the portal vein pressure does. There is a period following the ingestion of food during which the elevation of portal pressure appears to be unopposed by other forces.

Acute liver damage resulting from exposure to carbon tetrachloride vapor does not appear to be associated with a portal hypertension despite the fact that such livers appear congested upon examination. Such animals have shown a normal portal vein pressure response during exercise.

It is hoped that observations by this method in the intact animal may prove useful in studying the relationship of portal vein pressure to development of collateral venous channels and to ascites formation. It should also be possible to evaluate the reduction of portal pressure brought about by surgically created venous shunts in experimental cirrhosis.

*The plastic tubing used in these experiments is manufactured under the trade name "Transflex" and was furnished by the courtesy of Irvington Varalsh and Insulator Company, Irvington, N. J.

11. TREATMENT OF ENDOGENOUS HYPOVITAMINEMIA A IN LIVER DISEASE

HANS POPPER, M.D., FREDERICK STEIGMANN, M.D., AND HATTIE A. DYNIEWICZ,
PH.C. (BY INVITATION), CHICAGO, ILL.

Previous experiments have shown that the vitamin A metabolism in liver disease is altered in several ways. The release of vitamin A from the liver is disturbed since in acute liver disease, despite considerable hepatic vitamin A stores, the plasma vitamin A drops rapidly. This disturbance in vitamin A release is due to displacement of vitamin A within the liver cells as demonstrated by fluorescent microscopy. Another disturbance is impaired intestinal absorption as indicated by the flat vitamin A tolerance curve after oral administration of vitamin A. The endogenous nature of the hypovitaminemia A in liver disease points, therefore, to the necessity of administering extremely large doses of vitamin A or to correction of the faulty intestinal absorption. Administration of bile acids did not alter the flat tolerance curve.

In more recent experiments the administration of lecithin, wheat germ oil, and a fat-soluble antioxidant did not significantly or regularly raise the tolerance curve in hospital control subjects or in patients with liver disease. The administration of 50 mg. of mixed tocopherols simultaneously or for several days prior to the administration of 75,000 units of vitamin A also did not raise the curve significantly. This was confirmed by experiments on vitamin A-deficient rats in which the hepatic vitamin A concentration after feeding of one dose of vitamin A was not influenced by the simultaneous administration of tocopherol. In contrast, the hepatic vitamin A concentration after administration of repeated doses of vitamin A is far higher in animals receiving supplements of tocopherol. This points to a protecting mechanism of the latter within the liver.

Following recent reports about improved absorption of aqueous vitamin A preparations, the vitamin A tolerance curve was compared after administration of vitamin A in oil and in aqueous solution containing sorbitan monolaurate derivative as dispersing agent and propyl gallate as antioxidant. In twenty hospital control subjects and thirty-six patients with various liver disease (most of them with low plasma vitamin A), the tolerance curve after administration of 30,000, 75,000, or 600,000 units of vitamin A was much higher with the aqueous than with the oily solution, independent of the order of administration. The flat vitamin A tolerance curve in liver disease was thus raised to peaks above those found in hospital control subjects after administration of equal amounts in oil. The administration of aqueous vitamin A preparations therefore appears suitable for compensating the faulty absorption of vitamin A caused by liver damage.

12. STUDIES IN NITROGEN METABOLISM

D. KOZOLL, M.D., AND W. T. MOK, M.D. (BY INVITATION)
CHICAGO, ILL.

Influence of Oral and Intravenous Administration of Amino Acids Upon Nitrogen Balance.—A varied opinion exists as to the relative effectiveness of amino acids given by mouth and by vein, most workers indicating a slight advantage of the latter. Our clinical experience differed, and for that reason a study was carried out in which eight patients were given identical amounts of the same amino acid preparation by vein and by mouth and the nitrogen balance achieved compared. Each patient was kept on a 2,000 calorie diet which

was virtually nitrogen free for the entire period of study. For periods of five days each the patients were given quantities of a lyophilized amino acid preparation* intravenously and then the same quantity was given for another five-day period orally. In three of eight patients, oral administration produced a positive balance at the level of amino acids given, whereas the same quantity intravenously did not. In seven of the eight patients, the nitrogen balance during periods of oral administration was significantly higher than during equivalent periods of intravenous use. In one patient, in whom both routes produced positive balance, that produced by the intravenous route was significantly higher. This evidence indicates the advantages of the enteral route of administration of protein digests wherever possible.

Influence of Caloric Intake Upon Nitrogen Balance.—There has been established a concept that the degree of nitrogen balance will be greatly influenced by the caloric intake. Actually, few studies have investigated this particular point. In five patients a constant quantity of lyophilized amino acid preparation† was administered intravenously daily for five periods; this dose was calculated barely to approach nitrogen equilibrium. During each five-day period, the oral caloric intake, which consisted of a carbohydrate diet, almost free of protein, was varied between 500 and 3,000 calories. It was found necessary to administer a minimum of approximately 1,000 calories per day during each period to produce nitrogen balance. However, in no instance did an increase in the caloric intake beyond 1,000 calories lead to a consistently more positive nitrogen balance. This supports previous observations in which no consistent correlation could be made between the caloric intake of a given patient and the nitrogen balance achieved.

PROGRAM

SCIENTIFIC PROGRAM—OCTOBER 31, 1947

FRIDAY AFTERNOON, 2:00 P.M.

13. PENICILLIN IN THE TREATMENT OF ACTINOMYCOSIS

DONALD R. NICHOLS, M.D., AND WALLACE E. HERRELL, M.D.
ROCHESTER, MINN.

An appraisal of the value of penicillin in the treatment of actinomycosis is reported. The report is based on a review of ninety-eight cases of maxillo-facial, pulmonary, abdominal, and pelvic infection. The period of follow-up of these patients varied from one year to five years. Forty-five patients received penicillin; fifty-three patients did not receive it.

Of the group of patients suffering from maxillofacial actinomycosis, twenty-six received penicillin and twenty-five did not. Examination of the results reveals that the number who recovered was approximately equal in both groups (in excess of 90 per cent). However, the period of disability of those patients who received penicillin was markedly shortened. Furthermore, the sinuses healed within a short period after the institution of penicillin therapy.

From the standpoint of comparison between those patients who received penicillin and those who did not, the most striking results occurred in the pulmonary, abdominal, and pelvic infections. Nine patients suffering from pulmonary actinomycosis received penicillin. There were five recoveries and four failures. Of the thirteen patients suffering from pulmonary actinomycosis who were untreated or received treatment other than penicillin, seven died, five still had evidence of disease when last heard from, and only one showed evidence of improvement. Of seven patients with abdominal actinomycosis who were treated with penicillin, five recovered and two did not. Of fourteen patients suffering from abdominal actinomycosis who did not have the benefit of penicillin therapy, nine died, four still had evidence of disease when last heard from, and only one was said to have recovered. There were three patients suffering from actinomycosis involving the pelvic viscera, all of whom recovered after surgical drainage and penicillin therapy. There was one patient with pelvic actinomycosis in whom penicillin was not used. The treatment employed was not effective. Prior to the introduction of penicillin therapy, instances of pelvic actinomycosis in which cures were obtained were, in our experience, rarely if ever encountered.

The diagnosis of actinomycosis in each case was made by means of direct examination or culture of pus or of material obtained at operation. All strains of *Actinomyces bovis* cultured were found to be sensitive to the action of penicillin in vitro.

14. EFFECT OF PULMONARY EDEMA ON SUSCEPTIBILITY OF MICE TO PNEUMOCOCCAL PNEUMONIA

CARL G. HARFORD, M.D., AND MARY N. HARA, A.B. (BY INVITATION)
St. Louis, Mo.

Previous experiments have demonstrated that type I pneumococci are eliminated rapidly from the lung of the normal mouse but grow in the lung containing an influenza viral lesion. Histologic examination of the influenza viral lesion in the mouse has shown the presence of intra-alveolar fluid. The object of the present experiments was to determine whether this fluid could serve to explain the observation of growth of pneumococci in the viral lesion.

Advantage was taken of the facts determined by others, that in the normal animal, protein-containing fluids are removed slowly from the alveoli while crystalloids are absorbed within a few minutes. In confirmation of this slow removal, we have demonstrated in tissue sections that normal mouse serum instilled into the alveoli of normal mice will persist there for at least five hours.

Accordingly, normal serum or saline was given by intrabronchial cannula to groups of mice which then were allowed to inhale fine droplets of type I pneumococci and were observed for survival. In another experiment, the pneumococci were suspended in the inoculum of serum or in Locke's solution for control and the number of pneumococci in the left lobe of the lung determined three hours later in poured blood agar plates.

The results of all experiments indicated that the presence of serum in the alveoli rendered the mice more susceptible to fatal pneumococcal infection and interfered with the normal mechanism for elimination of pneumococci.

The manner of action of serum in the alveoli seems likely to be a combination of three factors: (1) interfering with surface phagocytosis, (2) providing a means of spread of pneumococci throughout the lung in the same way as the edema fluid of established pneumococcal pneumonia, and (3) supplying a culture medium for bacterial growth.

The experiments give evidence supporting the theory that the presence of alveolar fluid is an important factor in the mechanism by which the influenza viral lesion lowers resistance of the lung to secondary bacterial infection. The results suggest also that pulmonary edema in man due to any cause may bring about a greater susceptibility to pathogenic bacteria and pneumonia.

15. SURFACE PHAGOCYTOSIS OF TYPE III PNEUMOCOCCUS

W. BARRY WOOD, JR., M.D., AND MARY RUTH SMITH, M.S. (BY INVITATION)
St. Louis, Mo.

Surface phagocytosis, a defense reaction of the host unrelated to humoral immunity, has recently been shown to play an important role in the mechanism of recovery in acute bacterial pneumonia. Since type III pneumococcus produces a particularly virulent form of pneumonia, its behavior toward leucocytes has been studied both *in vitro* and in laboratory animals. Although experimental type III pneumonia in rats has been found to resemble type I pneumonia both in regard to pathogenesis and response to chemotherapy, it differs from the latter in that it frequently causes multiple lung abscesses. Also certain strains of type III pneumococcus, when given to mice via the respiratory tract, are less effectively destroyed in the lung and cause a significantly higher fatality rate.

A plausible explanation for the greater virulence of these type III pneumococci is suggested by the fact that they are more resistant to surface phagocytosis than is the type I organism. Evidence has been obtained that the increased resistance to surface phagocytosis is related to the presence of a peculiar outer capsule or "slime layer" possessed only by the highly virulent strains of pneumococcus III. The slime layer stains metachromatically with methylene blue and is present only on the surfaces of young, rapidly multiplying organisms. When the slime layer is lost with age, the bacterial cell loses its resistance to surface phagocytosis.

Of particular interest is the fact that pneumococcus type III loses its slime layer *in vivo* during chemotherapy. Once the outer layer is lost, the type III organism, like other encapsulated bacteria, is phagocytized by the surface mechanism and is ultimately killed and digested by the phagocytic cells. These findings would appear to explain certain well-established clinical observations concerning type III pneumococcal infections, particularly in regard to virulence and response to chemotherapy.

16. ANTIHYALURONIDASE ACTIVITY IN HUMAN SERUM WHICH INACTIVATES THE HYALURONIDASES OF TYPES I, II, AND VII PNEUMOCOCCI: RISE IN TITER FOLLOWING PNEUMOCOCCUS BACTEREMIA

ROBERT T. THOMPSON, M.D., CINCINNATI, OHIO
(INTRODUCED BY M. A. BLANKENHORN, M.D.)

A preliminary report on this subject was read at these proceedings two years ago. At that time rises in titer of antihyaluronidase activity which antagonized the hyaluronidases of types I, II, and VII pneumococci were reported in serial sera of five patients following pneumococcus bacteremia. These rises in titer occurred eight to twenty days after bacteremia and were not type specific. Further work on this problem, using the mucoprotein clot prevention test (McClean, 1943) as before, is reported here.

Including patients in the previous report, the serial sera of twenty-six patients with primary pneumococcal pneumonia had initial serum taken within three days of admission to the hospital. Results in these patients are reported here to indicate the occurrence of antihyaluronidase activity in the course of pneumococcal pneumonia.

None of seven patients with negative blood culture exhibited more than twofold rise of antihyaluronidase titer. Serial sera of two patients were titrated against the three enzymes, serial sera of four patients were titrated against two enzymes, and serial sera of one patient were titrated against one enzyme. Changes of antihyaluronidase titer found in these fifteen titrations were one-fourth-fold once, one-half-fold four times, no change five times, and twofold five times.

Eight of eleven patients with pneumococcus bacteremia and no purulent complication exhibited rises of antihyaluronidase titer which were fourfold or greater. Serial sera of all these patients were titrated against the three enzymes. Rise of antihyaluronidase titer found in these thirty-three titrations were no change once, twofold seven times, fourfold six times, eightfold eleven times, and sixteenfold eight times.

All of eight patients with pneumococcus bacteremia and purulent complications exhibited rises of antihyaluronidase which were fourfold or greater. Serial sera of all these patients were titrated against the three enzymes. Rises of antihyaluronidase titer found in these twenty-four titrations were fourfold six times, eightfold five times, sixteenfold three times, thirty-twofold three times, and sixty-fourfold or greater seven times.

One patient with mesothelioma of pleura complicated by pneumococci empyema and another patient with pneumococci meningitis secondary to otitis media had rises of antihyaluronidase titer.

These rises of antihyaluronidase titer probably signify excessive elaboration of hyaluronidase by the invading pneumococci, since the antigenicity of hyaluronidases has been demonstrated by McClean (1943). Hyaluronidases act as spreading factors (Chain and Duthie, 1939) so that this elaboration of hyaluronidase may explain the excessive morbidity and mortality of bacteremic pneumococci pneumonia.

17. EXPERIMENTAL AND CLINICAL INVESTIGATIONS ON THE SPECIFIC TREATMENT OF HUMAN BRUCELLOSIS*

WESLEY W. SPINK, M.D., WENDELL H. HALL, M.D. (BY INVITATION), JAMES SHAFFER, M.D.† (BY INVITATION), AND ABRAHAM I. BRAUDIE, M.D. (BY INVITATION), MINNEAPOLIS, MINN.

The fundamental requisite of successful therapy in human brucellosis is that brucella should be eradicated from the tissues. With this principle in view, this report summarizes a series of investigations which have been under way in the laboratories and clinics of the University of Minnesota Hospitals during the past ten years.

An excellent method for rapidly screening potential therapeutic agents has utilized fertilized chicken eggs infected with a virulent culture of *Brucella abortus* via the yolk sac. Uniformly lethal infections were established in seven-day embryos. With the inoculum used, 50 per cent of untreated controls were dead six days after infection, and 100 per cent, nine days after infection. When sulfadiazine was introduced into the sac twenty-four hours after the brucella, 50 per cent survived twelve days or more after infection. When streptomycin was injected, 50 per cent of the embryos survived nine to eleven days. When the embryos were treated with a combination of sulfadiazine and streptomycin, 50 per cent survived nine to eleven days. An important feature of these observations was not only the protection afforded by these agents, but also the results of cultural studies of the tissues. Brucella were recovered from all untreated controls. Sulfadiazine-treated embryos, when sacrificed, revealed brucella present in 90 per cent, while 77 per cent of the streptomycin-treated eggs contained brucella. Embryos receiving sulfadiazine and streptomycin showed brucella present in the tissues in only 13 per cent.

The foregoing data have correlated remarkably well with the results of therapy in patients having active brucellosis. Since an evaluation of treatment in this disease is dependent upon bacteriologically proved cases, studies have been carried out on thirty-five individuals from whose tissues or body fluids

*Aided by a grant from the United States Public Health Service.

†Research Fellow in Chemotherapy under a grant from Commercial Solvents Corporation.

brucella have been isolated. *Br. abortus* was recovered from thirty-three patients and *Brucella melitensis* from two. Sulfonamides, especially sulfadiazine, were used alone in twenty patients, and coincident with treatment complete recovery occurred in only six patients. Seven patients were treated with streptomycin and the results were less satisfactory than those obtained with sulfadiazine. Nine patients have been treated simultaneously with sulfadiazine and streptomycin with quite satisfactory results. One patient with subacute bacterial endocarditis due to *Br. abortus* recovered completely, except for a residual vertigo, and has remained well for four months after treatment. One patient with a severe and disabling spondylitis recovered promptly. The optimum dose of the two agents awaits further studies, but at the present time it is recommended that 0.5 Gm. of streptomycin should be injected intramuscularly every six hours for seven days for a total of 14 grams. Therapy with sulfadiazine is started at the same time with an initial oral dose of 4 Gm. and then 1 Gm. every four hours for two to three weeks. In conclusion, experimental and clinical investigations indicate that the simultaneous use of streptomycin and sulfadiazine will provide a more satisfactory form of specific therapy for brucellosis than has been described to date.

18. SIGNIFICANCE OF COPROANTIBODY EXCRETION DURING ENTERIC INFECTION*

PRESTON E. HARRISON, M.D., PH.D.
HOUSTON, TEXAS

(INTRODUCED BY JAMES A. GREENE, M.D.)

A study was made of fecal antibody excretion from patients with salmonella and shigella infections. Diarrheal and dysenteric stools obtained during the acute infection, recovery, and convalescence were examined for coproantibody simultaneously with culture and serum agglutinin titration. Positive cultures were obtained from 58.6 per cent of the patients and fecal agglutinins were found in 91.3 per cent. Coproantibody for the homologous organism, or for one or more enteric pathogens in those specimens from which a positive culture was not obtained, was demonstrated in high titer on several occasions from each patient. The antibody was present as early as the third day, reached peak titer by the tenth day, rapidly declined as recovery was initiated, and completely disappeared during convalescence. In those cases in which clinical recovery was not obtained, coproantibody persisted throughout the observation period. Circulating antibody did not rise to significant titer until about the time recovery was initiated and then gradually rose to high titer which persisted during the remainder of the observation period. Coproantibody titration provided a measure of efficacy of therapy in that following a good chemotherapeutic response coproantibody titer rapidly declined and disappeared when cultures became negative and after recovery definitely was established. In contrast, coproantibody persisted when clinical recovery was not obtained.

Coproantibody could be demonstrated only during active infection, or clinical activity of disease, and was not present in carriers who showed no evidence of infection. In chronic ulcerative colitis coproantibody for one or more species of shigella, and often for species of salmonella, was present during episodes of exacerbation of symptoms.

*Aided by a grant from the Committee on Scientific Research of the American Medical Association.

19. RESULTS OF VACCINATION AGAINST EPIDEMIC INFLUENZA DURING THE SPRING OF 1947

CLAYTON G. LOOSLI, M.D., PH.D., JAMES A. SCHOENBERGER, M.D. (BY INVITATION), AND G. BARNETT, M.S. (BY INVITATION), CHICAGO, ILL.

In the fall of 1946, a study was organized to test further the prophylactic value of vaccination against epidemic influenza. Two thousand twenty students living in university houses were employed. Seven hundred ninety were vaccinated and 1,230 served as control subjects. Three different commercial influenza vaccines, containing 50 per cent Lee, 25 per cent PR-8, and 25 per cent Weiss strains and prepared by the red cell eluate, calcium phosphate adsorption, and high speed centrifugation methods, respectively, were used. The number of students receiving the three vaccines was approximately the same. Vaccinations, given in the dormitories, were begun November 6 and completed December 6, 1946. The immune response to the three vaccine preparations was approximately the same as determined by the Salk modification of the Hirst chicken red cell inhibition agglutination test.

A sharp increase in the incidence of acute respiratory disease characteristic of mild influenza occurred among the student population during the first week of March, 1947. Antibody determinations for influenza A virus (PR-8 and Weiss strains) showed an increase in titer in convalescent sera from a portion of the unvaccinated patients admitted to the hospital. During the period of increased incidence (March 2 to April 5, 1947), the attack rate was the same (9.5 per cent) in the vaccinated (seventy-five) and unvaccinated (117) groups, with 2.5 per cent (twenty) and 2.36 per cent (twenty-nine), respectively, being admitted to the hospital.

Two strains of influenza virus, found to be closely related, were isolated from throat washings employing the egg technique. The sera of some of the patients admitted to the hospital, both from the vaccinated and unvaccinated groups, showed a marked rise in antibody titer against these strains. Antibody titers for influenza A virus (PR-8) in the acute sera of patients admitted from the vaccinated group were only slightly lower than the postvaccination levels. Sixty pairs of pre- and postvaccination sera were again tested for antibodies against the PR-8, Weiss, and Lee strains of virus as well as the new strains. There was an average of fourfold or greater rise in titer against the former and none against the latter. This shows that there was no close antigenic relationship between the new strains causing the epidemic and those making up the vaccine. This would explain the lack of effect of the vaccine in this outbreak of influenza. The problem of control of epidemic influenza in the light of the foregoing findings is discussed.

20. THE ROLE OF THE ADRENAL GLAND IN IMMUNE MECHANISMS

BENJAMIN C. HOUGHTON, M.D., J. S. THATCHER, M.D., AND
CAROLYN HILLES, COLUMBUS, OHIO

(INTRODUCED BY C. A. DOAN, M.D.)

Interest in the relation of the adrenal cortical hormone to the development and release of antibody globulin has been revived in recent years by the work of Dougherty, White, and associates. These authors have reported producing a remarkable augmentation of circulating antibody titers by the administration of

single large doses of adrenal cortical hormone to immunized animals. The anamnestic effect of this hormone exceeded, but was comparable to, the increase in immune titers induced by nonspecific protein and specific antigen administration. Since pituitary adrenotrophic hormone was also effective in this respect, it was suggested that the release of antibodies is a phenomenon mediated by the activity of the adrenal cortex. The concurrent reduction in total lymphatic tissues observed in treated animals led to the conclusion that the dissolution of lymphocytes effected by the concentration of adrenal hormone yields antibody globulin to the component proteins of plasma.

The question advanced by this work relates to the effect of the adrenal cortical function on the (1) formation, (2) release, or (3) distribution of antibody globulin. For the purpose of studying the hormonal effects upon the formation of immune bodies, two groups of cats were employed as experimental animals. One group was given suspended, washed sheep erythrocytes intravenously. The other group was adrenalectomized, maintained on 1 mg. of DOCA daily until adequate equilibrium was established, and then immunized against sheep erythrocytes in an identical manner. Titers of immune body developed in both groups without significant difference. Symptoms of anaphylaxis were exhibited by both groups upon re-exposure to antigen. Sodium ion levels were maintained without change in the adrenalectomized animals throughout the experimental period.

To study the effect of cortical hormone on the release or distribution of antibody globulin, three groups of immunized animals were used. These consisted of normal rabbits, normal cats, and adrenalectomized cats maintained on desoxycorticosterone acetate. Each group was subjected to a large single intravenous injection of whole adrenal cortical extract (Thatcher and Hartman). No augmentation of titers was observed at three, six, nine, or twelve hours, or subsequently. Realizing the possible differences in preparation, refinement, and content of hormone, this experiment was repeated using Wilson's whole cortical extract. Results were identical.

It is apparent, therefore, that the adrenal cortical hormones do not either affect the capacity of the animals to form immune bodies when exposed to antigen nor alter the titers of such immunity when it is established.

Hematologic studies carried out concurrently on normal immunized and adrenalectomized cats revealed wide individual variations in total lymphocyte levels. These levels, high or low, bore no relation to the capacity to form or maintain titers of immunity.

21. INSULIN DEPRESSION AND CARBOHYDRATE EXCITATION OF THE PANCREATIC ISLETS OF LANGERHANS

JEROME W. CONN, M.D., AND STEFAN S. FAJANS, M.D. (BY INVITATION)
ANN ARBOR, MICH.

Patients suffering from periodic spontaneous hypoglycemia produced by secreting islet cell tumors do not all yield the same blood sugar response to a test dose of glucose. About one-half of such patients have responded with a hyperglycemic, plateau (diabetic) type of curve, while the others have shown a normal or subnormal initial elevation of the blood sugar, followed by a rapid fall to hypoglycemic levels. Fasting hypoglycemia has been common to both groups. The discrepancy has aroused abundant speculation.

Our recent studies upon such patients have suggested that: (1) The presence or absence of the diabetic type of curve is dependent upon the functional

state of the islets of the pancreas proper. (2) The functional state of the pancreatic islets is conditioned by the intensity of the hyperinsulinism produced by the abnormal tissue; the more severe the hyperinsulinism, the more likely is pancreatic depression and a diabetic type of curve. (3) The amount of carbohydrate in the antecedent diet exerts an important influence upon the response.

The present experiments were designed to test these tentative conclusions. Dogs on constant diets were chronically hyperinsulinized with large daily doses of protamine zinc insulin for periods of four to eight months. Daily fasting blood sugar was maintained between 20 and 40 mg. per cent. Four-hour glucose tolerance tests were done weekly under a variety of conditions. The same animals were then made diabetic with alloxan, again hyperinsulinized as before, and the same experiments repeated. Differences in results before and after alloxan can be attributed to the presence or absence of the beta cells of the islets of Langerhans.

The results indicate:

1. The secretion of insulin by the pancreas can be greatly inhibited by long-continued administration of exogenous insulin, but sufficient insulin to produce severe, chronic hypoglycemia is required. Under these circumstances the blood sugar response to a test dose of glucose is of the diabetic type, even though there is sufficient steadily absorbed insulin acting during the test to have produced intense and prolonged hypoglycemia when no glucose was given over a similar test interval.

2. A small amount of insulin given intravenously at the height of the diabetic response to glucose produces a precipitous fall of the blood sugar. Thus the ability of the animal to respond normally to a sharp rise of the blood insulin level remains intact.

3. Insulin-inhibition of endogenous insulin production can be overcome in a few days by the administration of large amounts of carbohydrate despite continuation of the inhibiting dose of insulin. The hypoglycemic phase of the tolerance curve is restored.

4. Following alloxan destruction of the beta cells and the reinstitution of hyperinsulinism the blood sugar response to glucose is diabetic in type in the presence of the steady absorption of depot insulin. The precipitous fall of the blood sugar upon intravenous administration of insulin at the height of the blood sugar curve is again obtained. *However*, prolonged administration of carbohydrate in the presence of continued exogenous hyperinsulinism now fails completely to alter the fixed diabetic, plateau response to a test dose of glucose.

5. The former ability of the animal to convert an insulin-induced diabetic response to a normal one under the influence of high carbohydrate feeding is completely lost when the beta cells have been destroyed and are no longer capable of being stimulated to activity by high carbohydrate feeding.

6. The hypoglycemic phase of the glucose tolerance curve is dependent upon an active and rapid release of insulin into the blood stream in response to the physiologic stimulus for such release. This functional capacity of the beta cells can be depressed by exogenous insulin and awakened by high carbohydrate feeding, and the final response (within the limits of these experiments) is dependent upon the relative intensities of the depressing and awakening stimuli acting simultaneously.

22. THE DIFFERENTIATION OF INCIPIENT HYPERTHYROIDISM

ROY E. SWENSON, M.D. (By Invitation), and GEORGE M. CURTIS, M.D.
COLUMBUS, OHIO

The protein-bound blood iodine is of value in recognizing incipient hyperthyroidism associated with endemic goiter. It is a useful diagnostic tool in differentiating other conditions associated with an elevated basal metabolic rate, particularly when goiter is present.

For the region of Central Ohio, the average normal basal metabolic rate is -5 ± 8 per cent, while the average normal protein-bound blood iodine concentration is 0.88 ± 0.2 micrograms per 100 milliliters.

When 178 patients with untreated, uncomplicated nontoxic nodular goiter were grouped according to standard deviations from the average normal basal metabolic rate, it was found that the average protein-bound blood iodine progressively increased with each increment of the basal metabolic rate. A significant number of patients had basal metabolic rates of +3 per cent or above and protein-bound blood iodine concentrations of 1.2 micrograms per cent or above.

Of the uncomplicated cases, 66.8 per cent had symptoms suggestive of hyperthyroidism and of these, 70.6 per cent had elevated protein-bound blood iodine concentrations, while only 47 per cent had elevated basal metabolic rates. The protein-bound blood iodine was a better index of thyroid function than the basal metabolic rate alone. Symptoms listed according to their significant correlation to an elevated protein-bound blood iodine are: a pulse of 90 or more per minute, palpitation, weight loss, weakness, nervousness, and emotional instability. Of those with symptoms, 34.5 per cent had elevated protein-bound blood iodide concentrations associated with basal metabolic rates below +3 per cent. Here the incipient hyperthyroidism was unmasked by determination of the protein-bound blood iodine.

Because of the significantly elevated protein-bound blood iodine and the significant incidence of symptoms suggestive of hyperthyroidism in those patients with basal metabolic rates of +3 per cent or above, it is our conclusion that incipient hyperthyroidism is present in those patients with nodular goiter having (1) Basal metabolic rates of plus 4 per cent or above and protein-bound blood iodine concentrations of 1.2 micrograms per cent or above; (2) symptomatology suggestive of hyperthyroidism and a protein-bound blood iodine concentration of 1.2 micrograms per cent or above.

The basal metabolic rate is frequently elevated in association with certain cardiovascular diseases. When goiter is present, the protein-bound blood iodine is a useful diagnostic aid in evaluating thyroid function.

PROGRAM

SCIENTIFIC PROGRAM--NOVEMBER 1, 1947

SATURDAY MORNING, 9:15 A.M.

23. INHIBITION OF THE PRESSOR RESPONSE TO EPINEPHRINE INJECTION IN COMPLETE ANOXIA

A. SURTSUN, M.D. (By INVITATION), S. ROBBARD, M.D. (By INVITATION), AND
L. N. KATZ, M.D., CHICAGO, ILL.

We have recently observed an unexpected inhibitory effect of complete anoxemia on the pressor response to epinephrine. In the normal dog, an injection of 0.5 mg. of epinephrine intravenously causes a marked rise in arterial pressure which occurs within a few seconds and gradually diminishes during the next few minutes.

In open-chested dogs which are placed on pure nitrogen breathing, the oxygen tension of the blood falls very rapidly from normal to values approaching 0 volumes per cent within ninety seconds. During this period of developing anoxia the blood pressure tends to rise about 40 mm. Hg above the control level. The pressure then begins to fall steadily and this continues until death occurs, unless air breathing is resumed. When air breathing is reinstituted in the control experiments, a sharp postanoxic rise in arterial pressure is observed, this rise being somewhat similar in form to that seen after epinephrine injection in control animals.

The injection of 0.5 mg. epinephrine intravenously during the period of rising blood pressure in developing anoxia results in only a markedly diminished and very transitory rise in arterial pressure. If the anoxia is continued, the pressure falls as in the control anoxia experiments. If the injection is given after the pressure has started to fall in the advanced anoxic stage, epinephrine has no pressor effect and the late anoxic pressure decline continues. Reinstitution of air breathing now results after a brief delay in a typical epinephrine effect with the pressure rising to higher levels than those seen in the control post-anoxia rise.

These results suggest that in conditions of extreme anoxia such as might be seen in drowning or other forms of extreme asphyxia, the injection of epinephrine may lead to no change in arterial pressure inasmuch as the cardiovascular system seems to be incapable of responding to this pressor agent. As a matter of fact, our results show that under these conditions of extreme anoxia, endogenous pressor states exist which, upon the administration of oxygen in adequate amounts, would in themselves cause a marked rise in arterial pressure.

24. THE ROLE OF ARTERIAL PRESSURE CHANGES IN THE INDUCTION OF EPINEPHRINE-CYCLOPROPANE IDIOVENTRICULAR RHYTHMS

G. K. MOE, M.D., S. D. MALTON, M.D. (BY INVITATION), WALTER FREYBURGER, B.S. (BY INVITATION), AND BARBARA RENNICK, M.S. (BY INVITATION)
ANN ARBOR, MICH.

Ventricular extrasystoles, ventricular tachycardia, or ventricular fibrillation can be regularly produced in dogs under cyclopropane anesthesia by doses of epinephrine ranging from 1.0 to 10 micrograms per kilogram. Although the exact mechanism is unknown, it has been observed that dibenzyl-B-chlorethylamine (Dibenamine), which "reverses" the pressor action of epinephrine but does not abolish its chronotropic and inotropic actions, protects the heart against epinephrine-induced idioventricular rhythms. We have been able to demonstrate that Dibenamine prevents ventricular ectopic rhythms *because* it prevents the pressor response to epinephrine.

In dogs, doses of epinephrine which regularly produced ventricular automatism in the control periods failed to do so after the intravenous injection of 15 to 20 mg. per kilogram of Dibenamine. Clamping of the thoracic aorta, which raised arterial pressure by 50 to 100 mm. Hg, also failed to provoke idioventricular discharges in the Dibenaminized animal, but when small doses of epinephrine were followed within ten seconds by aortic occlusion, ventricular tachycardia resulted. After larger doses of epinephrine, which alone failed to arouse ectopic foci, ventricular tachycardia could be induced repeatedly by occlusion, and terminated by release, of the aorta.

In other experiments without Dibenamine, arterial pressure was controlled by means of a pressure stabilizer attached to the abdominal aorta. Doses of epinephrine which regularly established ventricular foci when the stabilizer was clamped off failed to do so when the pressor response was prevented by opening the stabilizer. For example, in one experiment 2 micrograms per kilogram caused a rise of pressure and ventricular tachycardia in control trials with stabilizer closed, but 16 micrograms per kilogram failed to disturb the normal sinus rhythm with the stabilizer open.

Although a rise of arterial pressure greatly facilitates the induction of idioventricular activity by epinephrine, the direct accelerator action of the drug is also important, for elevation of pressure alone will not usually produce more than occasional ventricular extrasystoles associated with reflex vagal slowing of the sinus node.

25. AXIS DEVIATION IN HUMAN BUNDLE BRANCH BLOCK

A. MORGAN JONES, M.R.C.P.* (BY INVITATION), MANCHESTER, ENG., AND
HAROLD FEIL, M.D., CLEVELAND, OHIO

We have noticed that, in a few cases in which bundle branch block appeared while the patient was under observation, there was little change either in the axis deviation or in the general pattern of the electrocardiogram. This study is an attempt to ascertain how far the axis deviation associated with bundle branch block is determined by the pre-existing electrical axis with normal conduction. From fifty-four patients, in whom both normal conduction and bundle branch block had been recorded, we were able to collect 192 records, ninety showing only bundle branch block, ninety-two showing only normal con-

*Rockefeller Travelling Fellow.

duction, and ten showing both bundle branch block and normal conduction complexes in all limb leads. In thirty-seven patients adequate chest leads indicated the side of the block, but in the remaining seventeen the side of the block was judged by the limb leads; there were thirty-three patients with left bundle branch block and twenty-one with right. The average position of the electrical axis with normal conduction and with bundle branch block was determined in each case by averaging the axis position in all available records with one type of intraventricular conduction.

In thirty-three patients who developed left bundle branch block, the average shift of the electrical axis associated with the block was 12 degrees to the left; in twenty-one patients who developed right bundle branch block the average shift of axis was 12 degrees to the right. In only twelve patients developing left and ten developing right bundle branch block was the axis shift 15 degrees or more. In the majority of instances the general patterns of the electrocardiogram was closely similar before and after the development of the block. Although there may have been changes in the electrical axis (due to alteration in the position of the heart, ventricular hypertrophy, cardiac infarction, or pulmonary embolism) between the normal conduction and bundle branch block records, these factors could have affected the apparent change of axis in either direction; there is, therefore, no reason to assume that they materially affected the average results, although they must be taken into consideration in individual cases. These extraneous factors can be excluded in the eight cases with normal conduction and bundle branch block complexes in the same record; the results in these cases were similar to those in the whole series.

It is concluded that the axis deviation and the general pattern of the electrocardiogram are not greatly modified by the appearance of bundle branch block and that the axis deviation associated with right and left bundle branch block is due principally to the position of the mean electrical axis of QRS before the bundle branch block appeared.

26. REGIONAL PRODUCTION OF MYOCARDIAL NECROSIS WITH ELECTROCARDIOGRAPHIC ANALYSIS

C. B. TAYLOR, M.D., O. H. AKRE, M.D., AND C. B. DAVIS, JR., M.D.
CHICAGO, ILL.

(INTRODUCED BY G. M. HASS, M.D.)

A new method has been used in producing myocardial lesions, resembling infarcts, in the heart of dogs. The heart is exposed surgically and a hypothermal instrument is applied to a selected area of the epicardium. Lesions, cylindrical in shape, and of controlled dimensions, are then produced by cooling the adjacent myocardium to a low temperature. Lesions of selected dimensions are reproducible in successive animals. Variations encountered in attempts by others to produce lesions by arterial ligation are never observed. Lesions have been repeatedly reproduced in several desired locations in the walls of the auricles and ventricles and in the interventricular septum.

Serial electrocardiographic tracings, using standard limb leads and varied precordial leads, have been obtained at brief intervals. Animals have been sacrificed at various stages in the healing of the lesions up to six weeks, beyond which time all electrocardiographic evidence of cardiac damage has disappeared.

Electrocardiographic analysis indicates that localization of lesions is often inaccurate when standard limb leads and precordial Lead IV are used. These leads are only capable of distinguishing between anterior or apical ventricular lesions and posterior ventricular lesions. Lesions of the right ventricle cannot

be distinguished from those of the left ventricle. The use of standard limb leads and a series of leads from the right and left of the midsternal line has resulted in accurate distinction between lesions of the right and left ventricles, either anteriorly or posteriorly. Evidence of myocardial damage is most pronounced when precordial leads are closest to the lesion. The more distant the leads, the less obvious the changes become. This rule holds only for the first three days. Thereafter, it becomes impossible, even by use of multiple parasternal precordial leads, to distinguish between lesions of the right and left ventricle.

It has not yet been possible to localize large lesions of the auricles or inter-ventricular septum, nor have persistent disturbances in conduction been produced.

27. DICUMAROL IN EXPERIMENTAL MYOCARDIAL INFARCTION

L. A. NALEFSKI, M.D. (BY INVITATION), AND GEORGE V. LEROY, M.D.
CHICAGO, ILL.

In a discussion of possible unfavorable side-effects of dicumarol in the treatment of myocardial infarction, the question was raised whether the hemorrhagic stage of the infarct might be more extensive as a result of the altered clotting activity of the blood. This study was undertaken to investigate the influence of dicumarol on the healing of experimental myocardial infarcts. The anterior descending branch of the left coronary artery was ligated in thirty-two dogs. Seven of these died within twenty-four hours. Dicumarol was administered to sixteen in doses sufficient to maintain the clotting activity of oxalated plasma between 40 and 25 per cent of normal. The remaining nine dogs were controls. The animals in each group were sacrificed from five to twenty-one days after the occlusion of the coronary artery. On gross examination there was no significant difference in the appearance of the infarcts at any stage in the two groups. Mural thrombosis was not found in any heart. Microscopic examination of representative sections did not disclose any obvious difference between the healing infarct in the treated dogs and the controls. Serial electrocardiograms showed no variation in the rate or the character of the evolution of changes associated with anterior infarction in dogs. The sedimentation rate of dogs' blood after coronary occlusion does not follow any consistent pattern, and no influence of dicumarol could be shown by it. Pleural and pericardial adhesions were present to about the same extent in each group of animals.

It is concluded that dicumarol therapy does not have any demonstrable deleterious influence on the healing of experimental myocardial infarction in dogs.

28. EXPERIMENTAL PULMONARY INFARCTION: THE ROLE PLAYED BY ABNORMAL PULMONARY CIRCULATION IN THE PRODUCTION OF INFARCTION BY EMBOLUS

DON W. CHAPMAN, M.D., PAUL A. WHEELER, M.D., AND LLOYD GUGLE, M.D.
HOUSTON, TEXAS

(INTRODUCED BY JAMES A. GREENE, M.D.)

Pulmonary infarction has never been produced consistently in experimental animals. Numerous investigators have found that obstruction of branches of the pulmonary artery is not in itself sufficient to result in infarction, if in-

infarction is defined to include necrosis of lung tissue. We have produced pulmonary embolus in twelve normal dogs by the release of venous thrombi and have produced pulmonary congestion in four dogs by the employment of alpha-naphtha-thiourea; pulmonary emboli and congestion were produced by combining these methods in eight dogs.

No infarction resulted in the twelve normal dogs in which intravascular clots were released. Pulmonary congestion was produced in the four dogs receiving alpha-naphtha-thiourea alone, but no gross or microscopic evidence of pulmonary infarction was demonstrable. Of the eight dogs which received alpha-naphtha-thiourea and emboli simultaneously, three developed pulmonary infarction distal to the emboli, and four showed, in addition, hemorrhage distal to the emboli. Apparently, obstruction of a pulmonary artery or one of its branches by an embolus does not cause infarction of the lungs distal to the obstruction because the blood supplied by the bronchial arteries is adequate to maintain nutrition. It appears, therefore, that if the bronchial circulation is interfered with by pulmonary edema or congestion, alveolar necrosis (infarction) results.

29. STUDIES ON VASOMOTOR TONE IN THE HYPERTENSIVE STATE*

S. W. HOOBLER (BY INVITATION), R. H. LYONS, R. B. NELIGH (BY INVITATION),
H. J. KOWALSKI (BY INVITATION), S. D. MALTON (BY INVITATION),
W. G. PAINE (BY INVITATION), C. H. MANRY (BY INVITATION),
J. T. MANNING (BY INVITATION), AND M. M. PEET
(BY INVITATION), ANN ARBOR, MICH.

Since in arterial hypertension the cardiac output is not usually decreased, it follows that there is an increase in total peripheral resistance. The locus of this increased resistance and its "neurogenic" or "humoral" nature are central problems in a study of the pathogenesis of this disease. The circulatory response to the autonomic blocking agent, tetraethylammonium, can be used in an attempt to quantitate the degree to which vascular resistance is dependent on vasomotor tone in the human subject since we have shown by plethysmographic studies that (1) the drug reduces resistance to blood flow in the limbs to the greatest extent in those areas which can be shown by paravertebral sympathetic block to be under greatest vasomotor tone, (2) reduction of vasomotor tone to a limb by body heating reduces the response to the drug, and (3) after sympathetic denervation of an extremity, peripheral vascular resistance is no longer altered by the drug.

Assuming, therefore, that decreases in vascular resistance after tetraethylammonium are in general proportional to the initial level of vasomotor tone, a comparative study was made of the effects of comparable doses of the drug on the resistance to blood flow in the feet and forearms of twelve hypertensive and twelve normotensive subjects. Resistance was calculated from the formula $R = \text{mean blood pressure (mm. Hg)}/\text{blood flow (ml./100 ml. limb/minute)}$. Reductions in resistance were equal in the two groups, thus suggesting that there was no increase in vasomotor tone in the extremities of hypertensive subjects.

The effects of the drug on the renal circulation were also investigated. Here it could be shown that in certain hypertensive subjects renal blood flow

*Aided by grants from Parke, Davis & Company, The United States Public Health Service, and the Life Insurance Medical Research Fund.

was maintained despite a fall in blood pressure. It would thus appear that increased vasomotor tone may play a significant role in the increased renal resistance of certain hypertensive subjects.

Since blood flow to other vascular areas is less susceptible to accurate measurement, conclusions regarding vasomotor tone from blood pressure observations alone must be accepted with some reservations since not only changes in peripheral resistance but also changes in pulse rate, arterial elasticity, and cardiac output may play a role in the depressor response to the drug. Two lines of evidence would indicate, however, that in other vascular areas than the extremities increased vasoconstrictor tone may be present in the hypertensive subject: (1) After exclusion of both lower legs and one upper extremity from the circulation by arterial tourniquets, the injection of tetraethylammonium still produces a blood pressure fall in hypertensive subjects but rarely in normotensive subjects; (2) after supradiaphragmatic splanchnicectomy the average response of the blood pressure to an injection of the drug is materially decreased.

These studies would seem to provide evidence that in some hypertensive subjects there is an increase in neurogenic vasomotor tone to the splanchnic or renal vascular beds but not to the blood vessels of the extremities.

30. THE EFFECT OF TETRAETHYLAMMONIUM CHLORIDE ON THE BLOOD FLOW IN THE EXTREMITIES OF NORMAL INDIVIDUALS

OWEN L. SLAUGHTER, M.D., HUGH S. BROWN, M.D., AND KHALIL G. WAKIM, M.D., ROCHESTER, MINN.

The effect of tetraethylammonium chloride on the blood flow in the extremities of seven normal individuals (four male and three female) was studied by the use of an air displacement plethysmograph with a compensating spirometer recorder. Tetraethylammonium chloride was administered to each individual intravenously in amounts of 300 to 400 mg. at the rate of 100 mg. per minute. All experiments were conducted in room temperatures which ranged from 80 to 85° F. (26.6 to 29.4° C.), but no single experiment was done in which there was a variation of more than 1° F. (1.8° C.) in room temperature.

With the subjects lying on the test bed, the plethysmographs were applied to the forearms and legs. The arm plethysmograph included the hand and forearm up to one inch above the olecranon process, and the leg plethysmograph included the foot and leg up to one inch below the tibial tuberosity. After the subject was well adjusted to the surroundings, determinations of blood flow were made for a period of about thirty minutes in order to establish a control level. The drug was then injected intravenously and records of the blood flow were taken for thirty to forty-five minutes thereafter.

The subjective symptoms, after administration of the drug, were a metallic taste, numbness and tingling, tachycardia, dryness of the mouth, and variable disturbances of vision with impairment of accommodation.

The average blood flow in the forearms of all seven subjects before the administration of tetraethylammonium chloride was 4.3 ml. per 100 ml. of limb volume per minute (range, from 1.7 to 7.3 ml.). After the injection of tetraethylammonium chloride the blood flow increased in every case, with a maximum increase occurring between five and fifteen minutes after injection (average about nine minutes). In all seven cases the average maximal blood flow in the forearms, after the injection of tetraethylammonium chloride, was 10.1 ml. per 100 ml. of forearm volume per minute (range, from 3.4 to 14.7 ml.). This rep-

resents an increase of 87 per cent in the average over the control flow. The average control blood flow in the legs of all seven subjects before administration of tetraethylammonium chloride was 3.2 ml. per 100 ml. of limb volume per minute (range, from 1.7 to 4.5 ml.). After injection of the drug the blood flow in the legs also increased in every case and reached a maximum at the same time as in the arms. The average maximal blood flow in the legs, after injection of tetraethylammonium chloride, was 6.9 ml. per 100 ml. of leg volume per minute (range, from 4.0 to 9.5 ml.). This represents an increase of 116 per cent over the control value (range, from 60 to 200 per cent). The increased blood flow in both upper and lower extremities gradually regressed; nevertheless, at the termination of the experiment (thirty to forty-five minutes after the administration of tetraethylammonium chloride), the flow still was higher than the control value. Accompanying the increase in blood flow there was a rise in cutaneous temperature.

31. THE NATURE OF THE COLD PRESSOR TEST AND ITS SIGNIFICANCE IN RELATION TO NEUROGENIC AND HUMORAL MECHANISMS IN HYPERTENSION

MORTON, P. REISER, M.D. (BY INVITATION), AND EUGENE B. FERRIS, JR., M.D.
CINCINNATI, OHIO

Previous evidence suggests that both neurogenic (autonomic) and humoral factors are concerned in the pathogenesis of increased arteriolar tone in clinical hypertension, but the exact nature of such mechanisms and their relative importance and interrelationships are not well understood. The present study is concerned with the effector mechanism of the cold pressor response in hypertension, utilizing varying degrees of sympathetic block induced by spinal anesthesia and tetraethylammonium chloride. The results clarify the effector mechanism of the cold pressor test and indicate that its utilization along with other procedures may be helpful in evaluating the relative importance of neurogenic and humoral components in patients with this disease.

In each of twenty hypertensive patients the cold pressor response was elicited in the usual manner and then repeated after the administration of tetraethylammonium chloride. One additional patient was tested in a similar manner four months after partial sympathectomy. In eight cases the response was again tested after high spinal anesthesia and in five of these repeated as the anesthesia receded to lower levels. In five instances the effect of tetraethylammonium chloride, was again tested following the performance of the test under spinal anesthesia.

Two phases of the blood pressure response to cold were noted: (1) the response during the minute of exposure to cold (cold minute), the classical cold pressor response, and (2) delayed pressor responses after the hand had been removed from cold water. In all cases tetraethylammonium chloride abolished the cold minute response, demonstrating that the effector phase of this reflex is neurogenic in character and indicating that the cold pressor response may be useful in evaluating procedures designed to eliminate autonomic tone in hypertension. Release of varying portions of the arteriolar bed from active vasomotor control (by spinal anesthesia) produced dampening of the response which tended to vary directly with the extent of denervation, but the smallest portion of the arteriolar bed which, under active vasomotor control, was capable of exciting clinically significant cold pressor reactivity varied from patient to patient.

In one case, who showed marked anxiety and resentment in response to the cold pressor test, there occurred following the cold minute exposure (during tetraethylammonium chloride action) a very sharp transient rise in pressure. Similar, but less marked, delayed transient elevations were seen in eleven other patients. Since such a pressor response occurs at a time when autonomic impulses are blocked at the ganglia, it must be the result of a humoral agent (the action of such agents not being eliminated by tetraethylammonium chloride).

Six (30 per cent) of the twenty patients failed to obtain a depressor effect from the administration of tetraethylammonium chloride, yet the cold pressor response was eliminated in each, suggesting that circulation of a humoral pressor agent, rather than failure of the drug to produce satisfactory autonomic blockade, was responsible for the absence of depressor response in these patients.

The data suggest that both humoral and neurogenic (autonomic) mechanisms may interact as clinically important factors in hypertension.

32. CIRCULATORY RESPONSES TO SPINAL AND CAUDAL ANESTHESIA IN HYPERTENSION: RELATION TO THE EFFECT OF SYMPATHECTOMY*

II. EFFECT OF RENAL FUNCTION

A. C. CORCORAN, M.D., ROBERT D. TAYLOR, M.D., AND IRVINE H. PAGE, M.D.
CLEVELAND, OHIO

In 1944 we found that the renal effects of high spinal anesthesia in patients with essential hypertension were variable. We suggested that the type of response of the renal vasculature might mirror the nature of the hypertensive process. Renal vasodilatation might then be taken as evidence of pre-existing increased vasomotor tone and failure of such vasodilatation as evidence of humoral vasoconstriction or of vascular rigidity due to renal arteriosclerosis. It was intimated that those patients who had predominance of vasomotor influence might receive more benefit from sympathectomy than would others.

The present report includes observations on the renal functional effects of high spinal anesthesia administered to seventeen patients with essential hypertension and of caudal anesthesia given to eighteen patients. Fourteen of the latter group had lumbodorsal sympathectomy.

The effects of spinal and caudal anesthesia upon renal hemodynamics were similar. Reduction of the average arterial pressure of hypertensive patients by 20 mm. Hg, to levels ranging from 85 to 125 mm. Hg, usually causes renal vasodilation, resulting in increased renal blood flow and a slight decrease in glomerular filtration rate.

Qualitatively the renal vascular response of normotensive and hypertensive patients to these procedures is identical. Quantitatively, they may differ slightly in that in hypertensive patients a fraction of afferent arteriolar resistance is not removed by anesthesia.

The renal vasodilator response to anesthesia in hypertension indicates that a large proportion of increased renal vascular resistance in this disease is dependent on nervous influences which are affected by anesthesia extending to about D 5, or alternatively that denervation by anesthesia has sensitized the vessels to vasodilator influences.

The major hemodynamic change induced by spinal or caudal anesthesia is seen to be due to decreased peripheral resistance.

*From the Research Division of the Cleveland Clinic Foundation.

Exceptionally, a few hypertensive patients show deficient or slowed renal vasodilator responses to spinal or caudal anesthesia. Two such patients failed to benefit from lumbodorsal sympathetic ganglionectomy, but operation was equally ineffective in patients whose responses were vasodilator. The renal vascular response to anesthesia is not a positive guide in the selection of patients, although the absence of vasodilation during anesthesia may contraindicate operation.

33. RELIEF OF CAUSALGIA BY USE OF TETRAETHYLAMMONIUM CHLORIDE

JAMES E. CONLEY, M.D. (BY INVITATION), HERMAN C. SCHUMM, M.D. (BY INVITATION), FRANCIS F. ROSENBAUM, M.D., AND FREDERICK G. GAENSLER, M.D. (BY INVITATION), MILWAUKEE, WIS.

Tetraethylammonium chloride was used for sympathetic blockade to relieve pain in seventeen patients with causalgia. The patients were selected on the basis of complaint of pain without consideration of trophic or vasomotor disturbances. In twelve patients pain was severe enough to prevent proper physiotherapy. Tetraethylammonium chloride was used primarily to obtain symptomatic relief.

Five patients with Sudeck's primary bone atrophy were given this drug in doses of 200 to 500 milligrams. This was sufficient to maintain comfort and to permit physiotherapy. Relief from pain appeared promptly and lasted several hours to forty-eight hours, even though complete sympathetic blockade was not produced. Follow-up clinical and radiologic studies showed improvement in the bone atrophy.

Two patients who were bedridden because of acute osteoporosis of the spine received relief from tetraethylammonium chloride which was comparable to that afforded by the use of narcotics. One of these patients was given 500 mg. to 2.0 Gm. in divided doses daily. She became ambulatory immediately with the additional aid of an orthopedic corset.

Three patients with bilateral thrombophlebitis whose walking was limited by cramps in the legs received extensive therapy with this drug. The relief from pain was not striking, although large doses were beneficial for short periods. The therapy did seem to help somewhat in restoring these patients to full activity.

Tetraethylammonium chloride was given to five patients with causalgia in the presence of known orthopedic disorders. These patients were selected because their pain seemed unrelated and disproportionate to the structural lesion. The bizarre pain was relieved, but the legitimate pain persisted. In two of these patients, swelling of the involved extremities decreased after tetraethylammonium chloride was given.

One patient with multiple pelvic fractures with bilateral pain in the legs had prompt relief of pain lasting about six hours after 225 mg. of the drug. This remission of pain permitted her to move the legs for the first time in nine weeks. Narcotics were required much less frequently thereafter.

A young woman with advanced scleroderma who had pain on motion of the fingers was able to use her hands with much less discomfort after moderate doses of the drug, but there was no significant change in the underlying disorder.

Tetraethylammonium chloride is of definite value in relief of causalgia. The relief of pain may be striking even though the sympathetic blockade is not complete enough to produce increased warmth and dryness of the extremities. The relief is usually sufficient to permit appropriate physiotherapy.

34. THE EFFECT OF DITHIOPROPANOL (BAL) ON HUMAN LEAD INTOXICATION

HENRY W. RYDER, M.D., AND ROBERT A. KEHOE, M.D., CINCINNATI, OHIO

Evidence has been accumulating in support of the hypothesis that certain heavy metals are toxic to biologic systems because of their reversible combination with the sulfhydryl groups of the protein fraction of cellular enzymes. There is some evidence that lead may be included in the group of metals that behave in this manner. Barron and Kalnitsky have shown that dithiopropanol (BAL) is one sulfhydryl-containing compound which is capable of reversing such an enzymatic inactivation due to lead. On the other hand, Braun, Lusky, and Calvery felt that lead and dithiopropanol exerted additive toxic effects in lead poisoning as induced experimentally in rabbits.

We have studied thirty men with acute episodes of lead poisoning, ten of whom were treated with dithiopropanol to the limit of tolerance. The drug has no dramatic immediate effect on the symptoms of lead poisoning. As a group the treated men had no different clinical course than the group of untreated men, except for the characteristic local and general effects of dithiopropanol and the occasional production, after prolonged therapy, of generalized muscular aching.

In contrast to the absence of clinical effect, the drug had unprecedented metabolic effects. Characteristically, the cellular lead concentration dropped sharply within a few minutes after the administration of BAL, continued to fall for an hour or longer, and returned to the previous level within twenty-four hours. The urinary lead concentration increased from several to fiftyfold within an hour or so. On the other hand, the lead concentration in the blood plasma of all the men was of a uniform order of magnitude, whether or not they had had abnormal lead exposure, clinical lead poisoning, or dithiopropanol therapy. The treatment did not change the fecal lead concentration or output.

While the changes in the lead concentration in the erythrocyte and urine were obtained again and again following repetitive administration of the agent, they were transient, and not enough lead was removed by the therapy to increase materially the total amount of lead eliminated by the subjects during the period of intermittent therapy or in the weeks that followed.

In summary we have observed that dithiopropanol is of no value in the treatment of acute poisoning in adults due to inorganic lead. We have observed also that the drug, in contrast to the lack of clinical effect on the symptoms of poisoning, causes a transient decrease in the erythrocyte lead concentration and a temporary increase in the urine lead concentration to a degree we have not seen with other types of therapy.

From these two observations we infer that the symptoms and signs of lead poisoning and the storage and elimination of lead may be due to mechanisms that are not intimately related. Our clinical experience in the lead trades supports this inference. The observed effects on lead metabolism are consistent with the hypothesis that lead combines with an erythrocyte component and that this combination can be reversed in vivo by dithiopropanol therapy, but the failure of symptomatic response to therapy does not give support to the theory that this particular enzyme system is involved in the mechanism of lead poisoning.

TO BE READ BY TITLE

35. CONGENITAL FAMILIAL HYPOPROTHROMBINEMIAS

ARMAND J. QUICK, M.D., MILWAUKEE, WIS.

The experimental evidence of the writer that prothrombin is a complex composed of several components suggests the possibility that more than one type of hypoprothrombinemia may occur clinically. This was borne out by studies of two families, in each of which several members have a hypoprothrombinemia. In the first family the mother, one son, and one daughter have a prothrombin time of $15\frac{1}{2}$ to 16 seconds. On mixing their plasmas with an equal volume of normal plasma, a mixture is obtained which has a prothrombin time of $13\frac{1}{2}$ seconds, the expected calculated value based on the writer's prothrombin curve. This type of hypoprothrombinemia is similar or identical with that produced by dicumarol poisoning. In this type of hypoprothrombinemia, it is component B which is reduced.

In the second family, two brothers are affected. Each has a prothrombin time of 19 to 20 seconds. Both have a bleeding tendency. When their plasmas are mixed with an equal volume of normal plasma, a normal prothrombin time (12 seconds) characteristically results. This same behavior has been noted with plasma from patients with avitaminosis K. When plasma from a member of family I is mixed with an equal volume of plasma from a member of family II, a prothrombin time of $13\frac{1}{2}$ seconds results, thus showing that the second plasma has the same corrective capacity on the first as normal plasma. In other words, the first plasma contains an excess of the factor lacking in the second plasma (component A), whereas the second plasma contains as much component B as normal plasma.

The prolonged prothrombin time resulting when oxalated plasma is stored is due to the disappearance of a principle that is neither component A nor B. It is not adsorbed by $Al(OH)_3$, $Ca_3(PO_4)_2$ and similar agents. This substance has been tentatively named the labile factor. Its lack in plasma may apparently cause a hemorrhagic diathesis as the recent report of Owren suggests.

The prothrombin time serves as a reliable guide of hemostatic efficiency even though it is dependent upon three factors: components A and B and the labile principle. A hemorrhagic tendency appears when the prothrombin time is 19 seconds or longer.

36. THE BLOOD COAGULATION-RETRACTION TIME AND ITS RELATION TO THROMBOSIS*

JOHN S. HIRSCHBOECK, M.D., MILWAUKEE, WIS.

Clot retraction is dependent upon thrombocytes, surface forces, erythrocyte mass, and qualitative and quantitative variations in fibrin. The same factors are also important elements in the development of the thrombotic tendency in individuals.

*Supported by a Grant-in-aid from the United States Public Health Service.

A method which measures the combined coagulation and clot retraction time of capillary blood was used in the study of 100 normal individuals, 100 post-operative patients, and 300 hospitalized medical patients. The coagulation-retraction time is determined by suspending a 20 c.mm. drop of capillary blood in castor oil. The drop is observed at five-minute intervals for the development of a bud of serum which projects into the oil from the retracting clot. The normal coagulation-retraction time is longer than 20 minutes, the average for 100 individuals being 33.1 minutes.

Patients in the postoperative period have shortened coagulation-retraction times. Approximately one-third of these patients had coagulation-retraction times less than 20 minutes during most of the postoperative period. Of the 300 general medical patients, 41 per cent had coagulation-retraction times less than 20 minutes and 11 per cent less than 15 minutes. One patient in this group developed pulmonary embolism when her coagulation-retraction time was 11 minutes (the shortest time observed in over 3,000 determinations).

The coagulation-retraction test is well adapted to the control of heparin therapy and can be used instead of the ordinary coagulation time determinations. The test is not reliable in following dicumarol therapy because its correlation with prothrombin time is not accurate. It is suggested that patients whose coagulation-retraction time is consistently less than 20 minutes be given prophylactic anticoagulant therapy.

37. THE EFFECT OF FOLIC ACID ON RADIATION INDUCED ANEMIA AND LEUCOPENIA

LEON O. JACOBSON, M.D., PHYLLIS STEARNER, PH.D. (BY INVITATION), AND
ERIC SIMMONS, PH.D. (BY INVITATION), CHICAGO, ILL.

Penetrating radiations originating external to the body and certain radioactive elements deposited within the body produce anemia, leucopenia, and other effects on the blood and blood-forming tissues when given in adequate doses. It is of interest that certain species develop a striking increase in mean corpuscular volume concomitant with the anemia after exposure to these physical agents. Experiments have been conducted on the human, rabbit, and rat in which attempts were made to modify these hematologic effects of radiations by the enteral and parenteral administration of folic acid. The penetrating radiation used in these studies was confined to x-ray (200 kv.) and was administered to the whole body in single (rabbits) or divided doses (human beings). The radioactive elements used were P^{32} (human beings) and Sr^{89} (rats) given intravenously in the former and intraperitoneally in the latter subjects. In certain of these experiments the folic acid was given before the radiation or radioelement was administered and continued. In others the folic acid was begun approximately at the point of maximum anemia or leucopenia or both and continued.

The anemias and leucopenias induced by these radiations were not prevented nor was recovery hastened by the administration of folic acid in adequate doses. The macrocytic anemia produced in rats by radiostromium and in human beings by total body x-radiation or radiophosphorus was likewise unaffected.

38. COMBINED SYSTEM DISEASE AND HEMATOLOGIC RELAPSE OCCURRING IN PERSONS WITH PERNICIOUS ANEMIA TREATED WITH SYNTHETIC FOLIC ACID (PTEROYL GLUTAMIC ACID) FOR A PERIOD OF TWO YEARS

RICHARD W. VILTER, M.D., CARL F. VILTER, M.D. (By INVITATION), AND VIRGINIA HAWKINS, R.N. (By INVITATION), CINCINNATI, OHIO

The observations presented have evolved from an extension and elaboration of studies undertaken in November, 1945, and reported at this meeting one year ago. Elucidation of the following questions has been sought: (1) Will synthetic folic acid given orally or parenterally control the anemia and glossitis of pernicious anemia and sprue for long periods of time as successfully as liver extract? (2) Will synthetic folic acid therapy prevent the development of the neurologic manifestations of pernicious anemia or control them after they have appeared?

Twenty-eight persons with pernicious anemia, the majority of whom had been controlled for two to seventeen years by injections of liver extract, were treated with folic acid orally for six months to two years. Folic acid treatment of twenty-four of these was begun on or about November, 1945; the remaining four have been treated six to eighteen months. Oral doses ranged from 30 mg. three times a week to 50 mg. daily.

Nine patients with pernicious anemia, six of whom were in relapse and three of whom previously had been maintained on parenteral liver extract, were treated with folic acid parenterally for six to twelve months. Doses ranged from 30 mg. daily to 30 mg. weekly. Three persons with sprue and one with macrocytic anemia secondary to ileosigmoidostomy were observed for nineteen to twenty-five months while receiving varying doses of folic acid orally. Complete physical and neurological examinations, erythrocyte counts, hemoglobin levels, hematocrit determination, and reticulocyte counts were performed at the beginning of the study and were repeated as often as the condition of the patient demanded.

So far, combined system disease has occurred in eight of the thirty-seven persons with pernicious anemia. During the first year four of the patients given folic acid orally developed posterolateral sclerosis after five to eight months of therapy. One of these showed mental deterioration. In the second year three patients on oral and one on parenteral therapy developed signs of posterolateral sclerosis, two with distinct mental changes, within four to eighteen months of the beginning of treatment. Satisfactory remissions followed the administration of liver extract intramuscularly.

Hematologic values have neither reached nor been maintained at optimum levels in the nine persons treated parenterally and one-third of the persons receiving folic acid orally developed moderate degrees of anemia. Gastric carcinoma and unexplained rectal bleeding accounted for the anemia in two of these. One patient had a striking hematologic and neurologic relapse after eighteen months of oral therapy (30 mg. three times a week). After intramuscular folic acid therapy for two weeks (30 mg. three times a week) the relapse continued unchecked. Erythrocytes had fallen to 1.51 millions and hemoglobin to 7.2 grams. Urine assays indicated that 50 to 80 per cent of the folic acid administered was excreted in the urine within twenty-four hours. The patient was given 12 Gm. of 5-methyl uracil daily for ten days. Reticulocytes rose to 10 per cent on the fourth day of this treatment and there was a

subsequent rise in red cells and hemoglobin to 2.45 millions and 9.5 grams. After discontinuance of 5-methyl uracil, complete hematologic and partial neurologic remission was achieved by parenteral liver therapy. Distinct glossitis occurred in five of the patients with pernicious anemia during folic acid therapy and waxed and waned without relation to the administration of the drug. The persons with sprue and secondary macrocytic anemia were maintained in better clinical and hematologic states than had resulted from liver extract therapy.

In conclusion, the second year of this study demonstrates that folic acid will not maintain hematologic remissions in all patients with pernicious anemia nor will it prevent the appearance of glossitis. In addition it confirms the previous observations that posterolateral column disease and mental deterioration may develop in persons with pernicious anemia even though their hematologic state is well controlled by folic acid.

39. TREATMENT OF PERNICIOUS ANEMIA WITH PTEROYL GLUTAMIC ACID (FOLIC ACID).

STEVEN O. SCHWARTZ, M.D., AND BERTHE E. ARMSTRONG, M.D., (BY
INVITATION), CHICAGO, ILL.

The paper is a résumé of experiences with folic acid in the treatment of pernicious anemia. The studies were begun in January, 1946, and over 100 patients have been maintained for varying periods of time on 5 mg. doses (daily). The discussion will center on such patients as have been either taken off the drug or maintained for twelve months or longer. In this category are sixty-nine patients. Of these, thirty-eight were men and thirty-one were women. The ages varied from 29 to 80 years. Six were placed on folic acid therapy immediately after an "assay period," while sixty-three were changed from routine maintenance liver therapy. Fifty-two are still on folic acid (as of September, 1947), four have disappeared from observation, and thirteen have been taken off the drug for the following reasons:

1. Hematologic relapse—five patients—during the sixth, seventh, eighth, twelfth, and thirteenth months.
2. Neurological relapse—four patients—during the second, sixth, eighth, and twelfth months.
3. Progressive anemia (not real relapse)—one patient—during the thirteenth month.
4. Refusal to take folic acid—one patient—because of "headaches."
5. Unreliability in taking folic acid—one patient.
6. Unreliability of subjective complaints—one patient.

It is concluded from the studies so far performed that 5 mg. folic acid per day is inadequate to prevent clinical, neurological, or hematologic relapses. Studies are now in progress evaluating the efficacy of 10 mg. per day.

40. EXOGENOUS HEMOCHROMATOSIS

STEVEN O. SCHWARTZ, M.D., AND SUNOLL BLUMENTHAL, M.D.

(BY INVITATION), CHICAGO, ILL.

Five female patients, with severe anemias due to miscellaneous causes, who received multiple transfusions and developed hemosiderosis and fibrosis of the liver were studied. The patients ranged in age from 19 to 75 years and were followed from nine months to four and one-half years. They received from twenty-one to seventy-five blood transfusions. With the evidence available from the study of the cases, together with a review of eight similar previously reported cases in the literature, the conclusion is reached that hemochromatosis in man can be experimentally produced by the administration of large amounts of iron (in the form of hemoglobin) if the iron is not secondarily lost from the body.

That the cases were not primary hemochromatosis is evidenced by the fact that the disease occurred in women, many of whom were young, and was accompanied by a severe anemia.

The pathogenesis of both idiopathic (endogenous) hemochromatosis and secondary (exogenous) hemochromatosis is discussed.

With the increased use of blood transfusions and the consequent lengthening of the anemic patient's life, the incidence of exogenous hemochromatosis will increase and will afford an opportunity to study a hitherto poorly understood disease entity.

41. MYELOMA CELL CYTOLOGY AS REVEALED BY HISTOCHEMICAL METHODS*

RAYMOND S. KIBLER, M.D., CHICAGO, ILL.

(INTRODUCED BY LOUIS R. LEMARZI, M.D.)

There has been no attempt made thus far to relate the cytoplasmic vacuoles, areas of hyaloplasm, and perinuclear clear area of the myeloma cells, as revealed by the Romanowsky stains, to the presence of preformed cytoplasmic organoids. In five cases of multiple myeloma of the "plasma cell" type, sternal marrow and air-dried marrow smears were studied by various cytologic and cytochemical techniques. By these means it has been possible to correlate cytoplasmic structures (mitochondria and portions of the Golgi element) with these cytoplasmic clear areas and, in part, to determine their chemical composition.

Marrow smears stained with Wright's and May-Grünwald-Giemsa stains indicated that these cytoplasmic clear areas (variously described by other authors) exhibited a series of distinctive patterns. Rodlike, filamentous, circular, and dotlike areas of hyaloplasm could be readily delineated. These light areas were found to be either diffusely scattered throughout the cytoplasm or congregated on one side of the nucleus, giving rise to a "Hof" or perinuclear clear zone.

Supravital studies on aspirated sternal marrow, utilizing neutral red and the neutral red-Janus green combination, demonstrated a variety of mitochondria whose form and distribution were identical with the clear areas noted in the stained smears. Neutral red vacuoles were present in all of the myeloma cells; however, they appeared to contribute but a small share to the total cytoplasmic pattern.

*Work done while Research Fellow, Department of Medicine, University of Buffalo School of Medicine, Buffalo, N. Y.

The Bensley-Cowdry mitochondrial technique revealed the presence of numerous mitochondria whose general configuration and distribution within the cells correlated with the observations made on supravital study.

The myeloma cells, when stained with the fat stains sudan black B and sudan IV, exhibited numerous sudanophilic organoids which were identical cytologically with the structures demonstrated by the aforementioned techniques. These bodies were not stained by sudan III, nor did they exhibit a positive Schultz reaction. They were stained by Nile blue sulfate; however, the staining was of the nonspecific type. In view of these negative findings, neutral fats, cholesterol, and cholesterol esters were excluded as being responsible for their sudanophilic properties. The organoids were stained by the Smith-Dietrich method, indicating their phospholipid nature.

The cytochemical test for vitamin A and/or its carotene precursors was positive and was precisely localized to the cytoplasmic organoids under discussion. Thus far it has been impossible to localize vitamin C within this group of cells.

All attempts at the cytochemical localization of the aromatic group of amino acids and the sulfhydryl-containing amino acids within these intracellular structures have been uniformly unsuccessful. A positive reaction for the free alpha amino acid groups has, however, been obtained.

Phase microscopy was used in this study as a method of providing a positive correlation between the mitochondria and neutral red vacuoles and the clear areas in the basophilic spongiosum.

It is concluded that (1) the areas of hyaloplasm in the myeloma cells are due to the presence of underlying mitochondria and portions of the Golgi element; (2) these structures have been found to be of a phospholipid nature; (3) vitamin A and/or the carotinoid pigments are localized to these areas; (4) these structures give a cytochemical reaction for free alpha amino acid groups.

42. BLOOD AND BONE MARROW FINDINGS IN RENAL DISEASE

IRWIN R. CALLEN, M.D. (BY INVITATION), LOUIS R. LIMARZI, M.D., CHICAGO, ILL.
AND HAROLD C. LUETH, M.D., OMAHA, NEB.

The association of anemia and renal impairment has been recognized for some time. Because the anemia is refractory to treatment and has no positive distinguishing characteristics, it has not been diagnosed in many instances. In addition there has been no agreement as to the hematologic findings.

In this study 102 patients were included, divided into 44 with chronic glomerulonephritis with azotemia, 22 without azotemia, 20 with essential hypertension, 6 with acute glomerulonephritis, 8 with miscellaneous kidney diseases, and 2 with extrarenal uremia. As a result of these studies it has been shown that anemia as demonstrated by the hemoglobin, red blood count, and hematocrit values, in general, is inversely related to the elevation of the nitrogenous waste products in the peripheral blood. The hemoglobin averaged 8.5 Gm. per 100 ml., the red blood count, 2,900,000 per cubic millimeter, and the hematocrit, 25 per cent, in cases of chronic glomerulonephritis, with an average nonprotein nitrogen of 123 mg. per 100 milliliters. The leucocyte count averaged about 12,500 in the cases of acute glomerulonephritis. Chronic types of renal disease showed borderline elevations of the leucocyte count. A slight increase in the relative percentage of stab neutrophils was also present in these respective cases. The average of the mean corpuscular volume, hemoglobin, and hemoglobin concentration in these studies proved to be within normal

limits for these groups. There were individual variations, but generally they involved the hemoglobin values and not those of the mean corpuscular volume as had been reported by other investigators.

A further correlation of the retained nitrogenous products and the values for the hemoglobin, hematocrit, and red blood count showed that in ten of the twenty-two patients with chronic glomerulonephritis without azotemia a significant variation was noted. Eight of these ten revealed a rise in one or two of the four blood chemistry determinations (nonprotein nitrogen, urea-nitrogen, uric acid, and creatinine).

The bone marrow, in contrast to some of the other published data, revealed a fairly adequate cellular picture with a myeloid-erythroid ratio near the normal in all the groups. The patients with acute and chronic glomerulonephritis with azotemia showed a slight increase in myeloid elements. The relative percentage of polychromatic normoblasts, however, was normal in all groups. The myeloid-erythroid layer, determined following centrifugation of 1 ml. of marrow blood in a hematocrit tube, was not increased in any of the groups except in acute glomerulonephritis. This increase was due to an increase in myeloid elements.

As a result of these studies, the following conclusions can be drawn: (1) anemia in renal disease is inversely related to the levels of nitrogenous waste products in the blood; (2) in cases where the anemia is borderline and renal disease is suspected, not only one, but complete blood chemistry studies should be done serially; (3) the bone marrow is relatively normal with some evidence of myeloid hyperplasia. Hypoplasia or maturation arrest of the bone marrow elements was not observed.

43. A STUDY OF THE MARROW IN ARTHRITIS

EUGENE F. TRAUT, M.D., AND STEVEN O. SCHWARTZ, M.D., CHICAGO, ILL.

Since evidence regarding the nature of arthritis has been sought often in the peripheral blood, it was thought advisable to study the most important blood-building organ, the marrow. We were interested in learning whether the marrow would help distinguish the two great groups of nonspecific chronic arthritis and whether the marrow findings paralleled the clinical progress in these conditions.

Forty arthritic patients were studied: nineteen atrophic, fifteen hypertrophic, two psoriatic, and four patients with rheumatic fever. These patients were in various stages of activity. Two of the patients with atrophic arthritis had 2 marrow studies.

One of us (S. O. S.) studied the marrows and gave a report without access to other clinical findings.

In general, the marrow mirrored the clinical impression gained otherwise. The marrow study gave further evidence of the inflammatory nature of atrophic (rheumatoid) arthritis as compared with hypertrophic arthritis. Complicating infections can cause the myelogram of degenerative joint disease to resemble that of inflammatory arthritis. The changes in the marrow reflect the course of disease in the joints.

The findings in the few patients with rheumatic fever suggest marrow studies as a measure of the activity of the rheumatic process.

44. RESULT OF METHYL-BIS (BETA-CHLOROETHYL) AMINE HYDROCHLORIDE THERAPY: A PRELIMINARY REPORT OF A NITROGEN MUSTARD

ROBERT A. HETTIG, M.D., HOUSTON, TEXAS

(INTRODUCED BY JAMES A. GREENE, M.D.)

Fourteen patients with confirmed diagnosis of lymphoma, leucemia, and multiple myeloma received single courses of methyl-bis (beta-chloroethyl) amine hydrochloride intravenously in the usual dosage.

Of six patients with Hodgkin's disease, two had an excellent remission and one a satisfactory response, whereas the remaining three improved either minimally or not at all. Nitrogen mustard administration provoked only partial remissions in two cases of lymphosarcoma and minimal improvement in two cases of chronic myelogenous leucemia. One patient with chronic lymphogenous leucemia obtained a rapid decrease in the leucocytosis without other evidence of benefit.

Two patients with severe skeletal pain due to multiple myeloma were improved symptomatically to a striking degree, but roentgen studies failed to demonstrate regression of the bone lesions. A case of mycosis fungoides was unaffected by nitrogen mustard therapy.

Nine patients of the entire series had received no previous treatment, whereas five had been subjected to varying amounts of roentgen therapy. In this limited clinical experience the previous use of irradiation did not appear to affect the response to the nitrogen mustard in an adverse way.

Excluding the three cases of leucemia, a significant leucopenia followed the administration of the drug in five patients (42 per cent of the series), but no ill effects ascribable to the leucopenia were detected. Nausea and vomiting occurred in 64 per cent of these patients during the course of treatment and constituted the only clinical evidence of toxicity in this series.

45. EXPERIENCES WITH URETHANE IN EIGHT PATIENTS WITH MALIGNANT DISEASE

LAWRENCE BERMAN, M.D. (BY INVITATION), ARNOLD R. AXELROD, M.D.

(BY INVITATION), E. A. SHARP, M.D., AND E. C. VONDER HEIDE, M.D.

DETROIT, MICH.

The therapeutic action and toxic effects of urethane have been studied in eight patients with leucemia and other neoplastic conditions. Oral administration was tolerated by most patients in doses of 0.5 to 6.0 Gm. daily over periods ranging from nine to fifty-four days. Total doses ranged from 26.5 to 221 grams.

No changes were noted in renal or liver function as observed by complete urinalysis, phenolsulphthalein, urea clearance, bromsulphthalein, hippuric acid, and cephalin flocculation tests.

There was little or no clinical improvement in three of four patients with leucemia exhibiting hematologic responsiveness and decrease in size of enlarged lymph nodes, spleen, or liver. Urethane did not affect the progress of terminal subacute leucemia, myelomatosis, or carcinoma of the lung. Although nausea and vomiting occurred frequently, there was no evidence that these symptoms constitute an indication for stopping urethane treatment. Weight loss out of

proportion to reduced food intake was noted in four patients and may represent an important constitutional injury to patients receiving urethane. Transient drowsiness and slight dizziness were observed.

Urethane caused a fall in the absolute numbers of both lymphoid and myeloid leucocytes in the blood of patients with normal or leucemic counts. The effect is greater on the more undifferentiated leucocytes. Severe temporary hypoplasia of all elements of the bone marrow may result from overtreatment and may progress after treatment has been stopped. Megakaryocytopoiesis persists longer than erythrocytopoiesis or leucopoiesis and appears to recover earliest after urethane therapy.

In the chronic leucemias, initial counts between 22,350 and 133,800 per cubic millimeter dropped to levels ranging between 1,900 and 12,000 per cubic millimeter after the patients received from 70 to 116 Gm. of urethane. One patient with chronic myelogenous leucemia exhibited a rise in the platelet count although the leucocyte count dropped to normal. There is no correlation between daily or total dose of urethane and the rate or extent of change of the total leucocyte count, lymph nodes, liver, spleen, or bone marrow.

No significant changes in reticulocyte percentages or color indices were observed. Anemia was favorably influenced in some patients although in others it became more severe.

There was regression of lesions in cases of mycosis fungoides and carcinoma of the skin.

On the basis of our studies it appears necessary to make bone marrow examinations, determinations of absolute leucocyte counts, and estimation of platelets, hemoglobin, and erythrocyte levels frequently.

46. BLOOD COAGULATION DURING INTRAVENOUS INJECTION OF HISTAMINE

STUYVESANT BUTLER, M.D., WILLIAM A. THOMAS, M.D., AND HEXWORTH N. SANFORD, M.D. (BY INVITATION), CHICAGO, ILL.

It has been recognized for some time that during peptone and anaphylactic shock and thrombocytopenic purpura there occurs a simultaneous clumping out of platelets and vasodilatation. Theoretically this dilatation occurs because platelets are no longer available for the removal of free histamine from the blood, and this histamine is the cause of the vasodilatation. Some investigators, however, believe that the platelets themselves are a source of some of the body histamine.

We have attempted to discover whether a continuously high level of histamine in the blood for many hours will materially effect the qualitative platelet count either by driving platelets out of the free circulation or by causing their increase in an attempt to overcome the increased histamine concentration.

Fifteen patients who received intravenous injections of histamine for migraine were used. Blood was drawn before the onset of each injection and six hours later, toward the end, using the technique of Sanford and Leslie. Blood was collected in chilled syringes, counted on a chilled chamber, and centrifuged in waxed chilled tubes. The coagulation times for whole blood, cell-free plasma, and platelet-free plasma were determined. Hematocrit and platelet counts were made simultaneously.

The histamine was given at a constant rate of 20 drops per minute in 500 ml. of normal salt solution, but the amount of histamine was almost doubled with each injection, 0.2 mg. being used for the first injection and 2.0 mg. of histamine base for the last.

Results.—

1. There was a definite shortening of the coagulation time in most cases which in total varied from 1.9 minutes to 1.0 minutes.
2. There was a correlation between the qualitative platelet activity and the coagulation time.

47. THE EFFECT OF CHRONIC ANEMIA ON RENAL FUNCTION AS MEASURED BY INULIN AND DIODRAST CLEARANCES

WILLIAM C. LEVIN, M.D. (BY INVITATION), RAYMOND GREGORY, M.D., AND
ALENE BENNETT, B.A. (BY INVITATION), GALVESTON, TEXAS

This study has been made as a means of evaluating renal function quantitatively in patients with chronic anemias. Inulin and diodrast clearances were determined in fourteen patients; a total of twenty separate studies were made.

In five patients with pernicious anemia, nine renal clearance studies were obtained. The average glomerular filtration rate was 73 ml. per minute as compared with a control average of 119 ml. per minute. The average renal plasma flow in the patients with pernicious anemia was 419 ml. per minute (control average, 640 ml. per minute). The average effective renal blood flow in these patients was 617 ml. per minute (control average, 1050 ml. per minute). These results reflect very definite decreases in glomerular filtration rate, renal plasma flow, and effective renal blood flow. However, the most striking abnormality is evident in the effective renal blood flow.

Eight studies in six patients with sickle cell anemia revealed an even greater reduction of glomerular filtration rate, with an average of 60.2 ml. per minute. The average renal plasma flow in this group was reduced to about the same degree as in the patients with pernicious anemia with an average of 398 ml. per minute. The effective renal blood flow was determined in only four instances; hence, the average of 386 ml. per minute is not comparable.

It is significant that the effective renal blood flow was definitely increased in two patients with pernicious anemia after remissions had been induced following the institution of specific therapy.

Chronic anemia may be associated with decreases in glomerular filtration rate, renal plasma flow, and effective renal blood flow. The impairment in glomerular filtration rate is more marked in patients with sickle cell anemia than in patients with pernicious anemia. There is a tendency for recovery of these functions toward normal in patients with pernicious anemia as a remission develops.

48. THE TREATMENT OF EXPERIMENTAL UREMIA BY INTESTINAL LAVAGE

BEVERLY H. WHITE, M.D. (BY INVITATION), AND HENRY N. HARKINS, M.D.
BALTIMORE, Md.

With the marked interest in peritoneal irrigation as a treatment of uremia, it was felt advisable to explore further the possibilities of intestinal irrigation despite a few unfavorable reports in the literature.

Isolated high intestinal loops (Thiry-Vella fistulas) were prepared in dogs and the intestinal continuity restored by end-to-end anastomosis. Eleven to twenty-eight days later a bilateral nephrectomy was performed. Five control dogs so treated died in from 52 to 104 hours following nephrectomy (average, seventy-three hours) and the terminal blood urea nitrogen levels varied from 145 to 265 mg. per cent (average, 193 mg. per cent). Six experimental dogs so treated, but, in addition, submitted to irrigations of the intestinal loop, died in from sixty-three to ninety-nine hours following nephrectomy (average, eighty-one hours) and the terminal blood urea nitrogen levels varied from 89 to 229 mg. per cent (average, 144 mg. per cent). It is thus seen that the duration of life in the irrigated dogs was not appreciably lengthened, probably because of a severe disturbance in the electrolyte pattern of the blood, which was only slightly relieved by calcium gluconate.

However, the average terminal blood urea nitrogen level was lowered by about 26 per cent. Furthermore, during the eighteen irrigation procedures to which the six experimental dogs were submitted, the blood urea nitrogen level was kept constant or was lowered in eight, or 45 per cent. The amount of urea nitrogen removed varied from 1.3 to 14 mg. per inch of intestine irrigated per hour. Best results in this regard were obtained with hypertonic fluids.

Conclusion.—Irrigation of intestinal loops will remove fairly large amounts of urea but does not appreciably prolong the life of the animals tested.

49. EXPERIENCES WITH THE MURRAY ARTIFICIAL KIDNEY

CONRAD R. LAM, M.D., AND JOSEPH L. PONKA, M.D. (BY INVITATION)
DETROIT, MICH.

At the 1947 meeting of the Central Surgical Association, Gordon Murray of Toronto described an artificial kidney with which he had had some success in the removal of nitrogenous products from anuric dogs and human patients. The principle was that of dialysis through a cellophane membrane. Blood was caused to flow through small-bore cellophane tubing which was immersed in a solution containing the dialyzable substances which it was desired to retain. The blood was removed from one iliac vein by a catheter inserted through the saphenofemoral junction and was allowed to return into the other iliac vein. Propulsion of the blood was obtained by a sterile pump arrangement operated by an electric motor. The dialysate was maintained at body heat and was agitated by a suitable mechanical device. A trap was provided to prevent air embolism.

We prepared an apparatus similar to that of Murray. The dialysate solution was that of Kolff of Holland. It had the following composition: NaCl, 0.6 per cent; NaHCO_3 , 0.2 per cent; KCl, 0.04 per cent; and glucose, 1.3 per cent. We have used the apparatus on ten nephrectomized dogs and two anuric patients. Approximately 2 Gm. of nonprotein nitrogen were removed each

hour from dogs whose blood nonprotein nitrogen was elevated to 100 to 200 per 100 milliliter. The chief adverse effect was related to the use of heparin, which is necessary to maintain the fluidity of the blood.

The first patient was a man, aged 21 years, with greatly diminished renal function due to repeated episodes of hemolysis. The artificial kidney was attached for eight hours, during which time his blood was dialyzed against 120 liters of solution. The initial nonprotein nitrogen was 260 mg. per cent. Although 27 Gm. of nonprotein nitrogen were recovered, the final nonprotein nitrogen of the blood showed a paradoxical increase to 294 mg. per cent. The run was discontinued because of serious bleeding around one of the catheters. The patient expired in pulmonary edema twelve hours after the apparatus had been disconnected.

The second patient was a man 52 years of age, with acute hepatitis and urinary suppression. He had been comatose for two days. It was questioned if the apparatus might serve as an "artificial liver" as well as an "artificial kidney." The apparatus was operated for twenty-nine and one-half hours; 81.6 Gm. of nitrogen were removed, the blood nonprotein nitrogen falling from 129 to 89 mg. per cent. There was no change in the blood sugar level, the chlorides rose from 365 to 427 mg. per cent, and the calcium reached the very low level of 3.5 mg. per cent. Fifty milliliters of 10 per cent calcium gluconate had been given to combat this calcium loss. At no time did the patient show clinical tetany. He expired eight hours after the run. No autopsy was obtained.

It appears that an apparatus of this type is effective to a limited extent in removing nitrogenous products. There is danger of hypocalcemia if the dialysate formula of Kolff is used.

50. LIPOID NEPHROSIS

WALTER M. BLOCK, M.D. (BY INVITATION), ROBERT L. JACKSON, M.D., AND
JOSEPH I. ROUTH, PH.D. (BY INVITATION), IOWA CITY, IOWA

Clinical and biochemical studies of forty-one children with lipoid nephrosis are evaluated. Twenty-six of the children are alive; nineteen have been entirely well for one to sixteen years, including three who had minimal hematuria on various occasions. Three have been well for less than a year and four still have active disease. Of twenty-two children who had received sulfonamides for infections, only three have died. Necropsy was done on ten of the fifteen children who died. Minor glomerular changes were seen in the kidneys of four children not known to have had hematuria. Pronounced glomerular changes occurred in two children who had minimal hematuria. Of the four children who did not show any glomerular changes, two had minimal hematuria on several occasions. Pathologic changes in the liver were minimal unless anæmia had been given.

Laboratory determinations revealed no significant alteration of the prothrombin time. Most of the increase in the blood fats was in the cholesterol fraction. The percentage of cholesterol esters was not decreased. In case of recovery, the cholesterol returned to normal values at a slower rate than the serum albumin. Blood fats reached values exceeding 5 Gm. per 100 ml. in some instances. No "critical edema level" for albumin was found. We have seen children free from edema with albumin values below 1 Gm. per 100 ml. and others with edema with values of 2.0 Gm. per 100 ml. The sedimentation test was a reliable guide in determining the course of the disease. Electrophoretic analyses of thirty plasma samples revealed uniformly low albumin values.

while the most pronounced change was the increase of the alpha 2 and beta fractions of globulin. During recovery, albumin increased, but the gamma globulin was slower in attaining normal values than the other fractions. No correlation was found between changes in the sedimentation rate and any individual protein fraction.

Choline citrate (0.8 Gm. each day) given to seven children for prolonged periods failed to produce essential changes in the blood fats or definite clinical improvement.

Periods of sudden change in edema were found to be critical times for the nephrotic child. Two children developed cardiac failure after the injection of large volumes of snerose.

Early diagnosis is important, for treatment is most effective in the early stage.

The prognosis is good since the advent of chemo- and antibiotic therapy and is not impaired by prolonged duration. Growth of the children who recovered was good.

(To be concluded in the December issue.)

COLLOIDAL GOLD CONTAINING THE RADIOACTIVE ISOTOPE Au^{198} IN THE SELECTIVE INTERNAL RADIATION THERAPY OF DISEASES OF THE LYMPHOID SYSTEM

C. W. SHEPPARD, PH.D., JAMES P. B. GOODELL, M.D., AND P. F. HAHN, PH.D.
NASHVILLE, TENN.

THE use of colloidal sols containing radioactive manganese in selective internal radiation therapy of diseases of the lymphoid system has been reported in an earlier communication.¹ In the report it was stated that other isotopes might be of therapeutic interest. More recently the release of radioactive isotopes from the chain-reacting uranium pile prompted us to consider the use of a different isotope since Mn^{52} was not available in therapeutic amounts from this source and since the wide choice of isotopes permitted a more favorable selection to be made. In making an appropriate choice it was required that the half life, radiation, and specific activity be suitable (with absence of long-lived contaminants and toxic effects), that the production cost be low, and that the chemical and biological behavior be familiar. These requirements were best met by the radioactive isotope of gold Au^{198} . In this communication the suitability of this isotope for therapeutic use will be discussed, and methods of preparation of the sol, dosage determination, and administration will be described. Clinical results are reserved for a separate communication now in the course of preparation.

HALF LIFE AND CONTAMINANTS

The half life of Au^{198} is 2.73 days.² We find that this rate of decay is ideal in therapy since the patient receives three-quarters of the radiation from a given dose in about five and one-half days. The therapist is then in a position to give additional treatment or not, at his own discretion. This permits rather good control of the radiation which is not possible in the case of longer-lived isotopes.

Practical considerations prevent the use at this time of isotopes of much shorter half life than Au^{198} . As decay rates materially increase, transportation must become increasingly rapid, and the possibility of preparing the colloid in one laboratory for delivery to another qualified center for administration is lost. Furthermore as the period of radiation decreases, biologically effective doses must increase, necessitating more elaborate precautions for the protection of the worker. Although not established there is reason to believe

Received for publication, July 1, 1947.

that the incidence of radiation sickness will increase as more intense doses of radiation are delivered over shorter periods of time.

Before any new radioactive isotope becomes acceptable for therapeutic use, the amount of long-lived contaminants present should be investigated. In the case of gold it is fortunate that no long-lived isotope of this element is known. Thus one must be concerned only with the presence of foreign elements in the original gold from which the isotope is prepared. Those most likely to be present are silver and copper. Traces of silver may give rise to the 225 day isotope of this element. For this reason a decay study was made on a sample of the gold containing the isotope. The decay was first investigated by following the gamma radiation with a Lauritsen electroscope; later the decay was followed by measuring the activity with a Geiger-Müller counter which is predominantly sensitive to the beta rays. It was found that the decay curve was strictly exponential for well over ten half lives at which time the activity became too weak to follow. This is a "clean" isotope only because gold of suitable purity was activated in the first place.

CHEMICAL AND BIOLOGICAL BEHAVIOR

The chemical behavior of gold is as familiar as that of most elements and the preparation of colloidal suspensoid sols of this element is extremely simple. Such sols are stable and will withstand repeated autoclaving at 120° C. They can be concentrated by boiling, and a reasonable amount of dissolved salts does not appear to affect the stability. This is in definite contrast to our experience with sols of manganese oxides which must be dispersed under sterile conditions since they do not withstand subsequent sterilization.

The biological behavior and toxicology of ionic gold are well known. The literature on colloids is less complete. However, the distribution in the rat of intravenously administered colloidal gold sulfide has been studied.³ Our own investigation⁴ has shown that, in the human being, particles of intravenously administered colloidal metallic gold are phagocytosed by reticulo-endothelial cells, with a higher concentration in the spleen than is obtained with manganese. If we assume that it is desirable to irradiate this organ rather completely in most instances the latter feature is a desirable one. In the present case the toxic effects of ionic gold present no problem. Due to the insolubility of metallic gold blood levels are low following its deposition in the body. An additional safety factor is achieved by limiting the amount of gold to 4 mg. or less per dose. In the course of considerable clinical experience we have never observed any effects which might be attributed to gold toxicity.

RADIATION EMITTED

Au^{198} emits negative electrons with a maximum energy of 0.78 mev and two gamma rays with an energy of 0.28 and 0.44 mev have been found.^{2, 5} Although a hard 2.5 mev gamma ray is reported it is not intense enough to make shielding difficult. Two inches of lead give ample protection for the largest amounts involved and considerably thinner shields suffice in many in-

stances. The gamma rays are penetrating enough to permit external tracing of activity in the body of the patient by the use of a directional Geiger-Müller counter. Recent studies would indicate that some features about the disintegration of Au^{198} still require further clarification.⁵

PRODUCTION OF RADIOACTIVE GOLD

The isotope is provided by the Atomic Energy Commission and is prepared by exposing metallic gold to the flux of slow neutrons in the chain-reacting pile at Oak Ridge. The reaction is

The simultaneous factors of abundant parent isotope, high capture cross section, and high neutron flux place this isotope in the high range of specific activities produced by the pile. It is this which permits such high and therefore therapeutically effective radiation doses to be administered in such small amounts of gold. At the present time the limitation in production is set primarily at quantities which may be safely shipped. Even with this limit the cost is roughly only two to five dollars per dose.

PREPARATION AND ADMINISTRATION

The chemical procedure in the case of radioactive gold is extremely simple. No radiochemical separation is required. It is merely necessary to convert the metallic gold to a solution of gold chloride (probably aurochloric acid) and to reduce this once more to metallic gold in alkaline solution by adding ascorbic acid. The presence of gelatin, although not essential, increases the reliability of the procedure.

Gold foil (16 mg.) containing radioactive gold is transferred to a long-necked Kjeldahl flask provided with a female ground joint. This is supported behind two-inch lead bricks and is viewed in a mirror. A few drops of aqua regia are sufficient to dissolve the metal. The solution is then evaporated to dryness. Since high temperature decomposes the gold salt, the flask is evacuated by inserting a male ground joint connected to a vacuum pump. The flask is heated with a water bath and because of its rounded shape safely withstands evacuation. After drying is complete, 50 c.c. of pyrogen-free water and $\frac{1}{2}$ c.c. of Knox P-20 gelatin* are added. The solution is made alkaline by adding 1 to 2 drops of concentrated KOH. A solution of 25 mg. ascorbic acid in 10 c.c. of water is then added; a deep red colloid forms instantly. In all operations the use of long pipettes and tongs provides added safety for the worker. Individual doses are dispensed from a simple pipette constructed from a 50 c.c. Pyrex graduated centrifuge tube of the conical type. The dispensing tip is attached to the bottom of the tube. Its long S shape permits withdrawal from the long-necked flask while the pipette rests behind the protecting lead shield. The open top is drawn down to a small diameter and is connected through a rubber tube to an external syringe by which the pressure may be controlled

*Furnished by Dr. D. Tourtellotte of the Knox Gelatin Protein Products Co., Camden, N. J.

from outside the shield. The volume of liquid may be observed in the mirror. Doses are dispensed into penicillin bottles which are placed in lead-carrying shields. These provide protection during autoclaving and local transportation.

Intravenous administration is facilitated by the use of a saline infusion. The saline solution is run into the cubital vein in the usual manner and after satisfactory flow is established the sol is poured into the solution by the use of tongs. This technique permits the maintenance of a safe clearance at all times.

THE DOSAGE UNIT

The radioactivity of each dose is determined by measuring the gamma ray intensity at a distance of 1 M., using a Lanritsen electroscope.* Measurements are made on an ordinary laboratory bench which introduces minor uncertainties in the radioactivity of samples of variable size and shape due to scattering and to absorption effects. However, studies have shown that the accuracy is sufficiently good for therapeutic work. Sufficient material must surround the sample to remove all beta rays. This is achieved by placing the sample container in a large glass beaker.

Pending the establishment of accurate milliecurie standards of radioactive gold it was decided to adopt an empirical dosage unit. This was the amount of radioactive gold which produces a discharge rate of 0.5 small division per minute on our electroscope. The radium discharge rate determined by the manufacturer for this instrument was 2.14 small divisions per minute per milligram of radium at 1 meter. This figure should suffice to compare our instrument with others from this source. However, the lack of sufficient information concerning the technique of their measurement makes the value unreliable in absolute amount.

Before the absolute decay rate for a given sample of Au^{198} can be established with certainty it will be necessary to investigate the decay characteristics of the isotope further. However, if it can be assumed that the two gamma rays of Au^{198} are emitted in cascade at each disintegration and that the effect on the electroscope of each quantum is proportional to the energy of the quantum, it may be estimated from the response of the instrument to accurately calibrated radium needles of known filtration that one unit is roughly 0.3 millieuries. This estimate is subject to a number of uncertainties. In any event, conservative initial dosage is recommended in order that the response to radiation can be established to the satisfaction of the therapist.

SUMMARY

Colloidal gold containing the radioactive isotope Au^{198} has been used in therapy of diseases of the lymphoid system. The material is obtained at low cost from the chain-reacting pile at Oak Ridge. The isotope has an ideal half life and good radiation characteristics. The chemical procedures are simple, and extremely stable colloids can be prepared. Toxicity effects due to gold are

*Manufactured by the Fred C. Henson Co., Pasadena, Calif.

not encountered. The technique for preparation, dosage measurement, and administration is described. Clinical results are reserved for a later communication.

We wish to thank the Isotopes Branch of the United States Atomic Energy Commission and the cooperative personnel of the Clinton Laboratories who made possible the use of the radioactive material investigated in this research.

DIRECT INFILTRATION OF RADIOACTIVE ISOTOPES AS A MEANS OF DELIVERING IONIZING RADIATION TO DISCRETE TISSUES

P. F. HAIN, PH.D., J. P. B. GOODELL, M.D., C. W. SHEPPARD, PH.D.,
R. O. CANNON, AND H. C. FRANCIS, M.D.
NASHVILLE, TENN.

ELSEWHERE^{1, 2, 4} we have described the use of radioactive colloids of Mn^{54}O_2 and Au^{198} in an attempt to radiate specifically the lymphoid-macrophage system. The MnO_2 sols were found to be gradually liberated, with evidence of secretion by way of the biliary tract. In the case of the gold sols, however, it was found by use of a directional type of counter³ that the radioactive material remained in the tissues in which it had been deposited (that is, chiefly the liver and the spleen) for as long as measurements could be made.⁵ Because of the chemical characteristics of metallic gold it was felt advisable to determine whether the insolubility of gold colloids in body fluids could be used to advantage in direct infiltration of neoplastic tissue.

When radium needles or radon seeds are implanted in tissue in order to provide localized radiation, it is necessary to filter the alpha and beta emanations in order to avoid too intense radiation immediately about the needle or seed itself. Dependence is then placed on the cross fire of gamma radiation to the affected tissue, but some radiation of the adjacent normal structures cannot be avoided. In utilizing the radiation from colloidal sols directly infiltrated into the tumor tissue, many millions of "point sources" of radiation are involved in emitting beta rays diffusely throughout the injected volume of tissue. Since the mean free path of the beta ray is of the general order of a millimeter, any considerable irradiation of normal surrounding tissue is avoided. In the case of either Au^{198} or Au^{199} isotopes one is not too greatly concerned with the gamma radiation per se since the ionization produced is not of great consequence in comparison with that derived from the beta radiation. However, the gamma radiation is of particular value in enabling the investigator to measure the localization and relative degree of concentration of infiltrated material.

Certain metastatic lesions are so vascular that injection results in effecting an intravenous administration of the colloidal particles, as will be seen in at least one instance below.

Also, some tumor tissue has been found to be so friable or otherwise constituted that it will not contain even relatively small volumes of fluid. In such instances the procedure as outlined in the foregoing becomes untenable. Under such conditions it is felt that resort to other procedures must be taken in order to establish the radioactive material at the desired site. Preliminary investigations are under way to determine whether the propensity for silver to become

From the Departments of Biochemistry, Medicine, Obstetrics and Gynecology, and Radiology, Vanderbilt University, School of Medicine.

This work was carried out under a grant from the Donner Foundation.

Received for publication, Aug. 22, 1947.

fixed to tissues might be employed to circumvent this problem.^{7,9} Several possible reactions are involved: (1) Reduction of the radioactive silver when injected as the Ag^*NO_3 salt to metallic silver with relatively permanent fixation by the tissue by the presence of reducing materials such as glutathione and ascorbic acid; (2) precipitation of the silver as a chloride by interaction with tissue chlorides; and (3) combination of the silver with the tissue proteins to form relatively insoluble compounds. Silver colloids, especially that of the oxide, also seem promising at the present writing.⁹

Possibilities involved in the use of radioactive silver are legion. Topical application of radioactive silver nitrate is a logical and reasonable approach to irradiation of superficial lesions.

Because Ag^{111} is a pure beta emitter, it is not possible to apply adequately external measurement apparatus for determination of the localization or intensity of radiation from the material deposited deeply in the tissues. This may be circumvented in part by adding small tracer quantities of long-lived $\text{Ag}^{108,110}$, but such a procedure must be considered carefully because little is known regarding the rate of removal of silver from tissues under such conditions. In the case of superficial tumors which, following radiation, can be reliably expected to slough off, such a procedure might be justified. The experimental preliminary studies demonstrating the localization of silver in tissues will be reported elsewhere.^{7,9}

METHODS

The preparation of the colloidal sols has been described earlier.^{1,4} Ordinarily the gold sols for intravenous administration were made up to contain 2 Vanderbilt units (V. U.) per milliliter. Such concentrations of radioactivity were usually found to be too low for infiltration work because of the necessity of injecting relatively large volumes of solutions. Therefore the gold colloids were concentrated by boiling so that 5 or more units per milliliter were obtained. The stability of these colloids allows this to be done successfully. It might also be equally practicable to make up the colloid in a smaller volume of solution originally, although difficulties due to "clumping out" of the gold have been encountered occasionally upon attempting to do this.

The "Vanderbilt unit" represents what we estimated at an earlier date to be an approximation of a millicurie and it is an arbitrary unit of dosage. It is now felt to represent nearer $\frac{2}{3}$ millicurie. The material is measured at one meter with adequate shielding of beta radiation so that the gamma radiation from Au^{198} only is read on a Lauritsen, radium calibrated electroscope.⁷ Under such conditions a single "Radiation Unit" obtained from Oak Ridge, consisting of 16.0 mg. of gold foil, which has been exposed to a flux of slow neutrons, would have on an average of about 120 V. U. at time of removal from the uranium pile. It has been found that approximately 40 V. U. of Au^{198} administered by vein to an adult of average size may result in a remission in chronic lymphocytic leukemia.⁸ However, it must be kept in mind that there is a considerable amount of individual variation in response to such therapy.

In the cases of discrete encapsulated lesions, the colloid was administered in the same manner as would be employed for infiltration of a novocain solution. The long needle, preferably of small caliber was inserted the maximum desired distance into the tissue and the sol released gradually as the needle was withdrawn.

Following infiltration, frequent measurements were made using the directional counter.³ This instrument consists of two gamma sensitive Geiger-Müller tubes enclosed in about an inch-thick cylindrical lead shield. One of the counters is positioned opposite a removable

*Obtained from the Fred C. Henson Co., Pasadena, Calif.

port whose opening may be varied from one-fourth to three-fourths inch. The other is completely shielded by the lead. The output of these tubes is fed into two counting rate meters which, by an appropriate circuit, are made to subtract. The degree of directionality obtained is quite high. One is able to find the edge of the liver or spleen with ease, and maintenance of injected material in nodes or tumor masses can be readily followed. The whole shielded tube is mounted in a carriage which permits ready translation on all axes as well as rotation.

CLINICAL OBSERVATIONS

E. R., a 28-year-old white man, had been treated for Hodgkin's disease at various times since November, 1945, with x-ray, radioactive colloidal manganese dioxide, nitrogen mustard, and radioactive colloidal gold, respectively. The patient showed good general response to radiation therapy except that there were two persistent enlarged lymph nodes in the right posterior cervical chain. The larger of these measured 3 by 2 by 1.5 cm. and the smaller measured 1 by 1 by 1 cm.; 0.25 ml. (1 V.U.) of colloidal radioactive gold sol was injected into the former and half that quantity into the latter by infiltration. The patient complained of a burning sensation at the site of injection for about one minute, after which the pain ceased. Daily examinations during the ensuing week revealed no swelling, redness, or increased heat in these areas, although there was some tenderness on pressure. One week after the injection there was no decrease in the size of either node. At this time the larger node was infiltrated with 1.5 ml. of the gold sol containing 5 V.U. and the smaller with 0.3 ml. containing 1 V.U. About three hours after injection the patient complained of aching pain in these areas. Redness, swelling and tenderness developed, reaching a maximum in about twelve hours, and gradually subsided. The patient was discharged and was not seen for four months at which time he was readmitted to the hospital. There was an area measuring about 2 by 2 cm. in the right lateral cervical area directly over the site of gold injection which showed a bluish discoloration. There was a slight tenderness in this area and a small pea-sized, nontender, firm node was palpable just inferior to the area of discoloration. No other lymph node enlargement was observed.

H. H., a 57-year-old white man, had had a long standing bronchiectasis and known generalized lymph node enlargement of three years' duration. On Mar. 6, 1946, biopsy of an axillary node revealed lymphosarcoma. Intravenous therapy with radioactive colloidal manganese dioxide was begun and an enlarged lump over the left clavicle diminished somewhat in size as did most of the lymph nodes. There was marked subjective improvement. He was given occasional intravenous injections of colloidal MnO_2 and later of colloidal gold. On Feb. 12, 1947, he was admitted to the hospital for blood transfusion and at this time the supraclavicular mass measured 14 by 12 cm. and was elevated 3.5 cm. above the surface of the surrounding skin (Fig. 1). Seven V.U. of colloidal radioactive gold in 7.0 ml. of solution were infiltrated diffusely into the center of the mass. The patient noted a sensation of constriction in the area for several hours, but no other symptoms were subjectively felt and over a period of twenty-four hours there was no tenderness, increased heat, or redness. A week later there was a definite decrease in the size of the mass centering about the injected area and it was softer. Measurement showed the mass to be 12 by 10

centimeters. Use of the directional counter for measurement of gamma ray activity showed good localization of the radioactivity in the mass. At this time an additional 12 V.U. of sol in 9.0 ml. of solution were infiltrated into the tumor tissue in the upper mid-portion; the patient again complained of a feeling of

Fig.1.—Fibrosarcoma prior to treatment.

Fig. 2.—Fibrosarcoma four weeks later.

tightness and constriction but nothing else. Another 14 V.U. were infiltrated on Feb. 26, 1947, and an additional 7 V.U. on Mar. 19, 1947.

The infiltrated mass had completely disappeared at examination on April 1, 1947 (Fig. 2).

G. S., a 35-year-old white woman (gravida ii, para i, abortus i), was admitted to the gynecologic service May 5, 1947. Five months previously she had received a supravaginal hysterectomy and bilateral salpingo-oöphorectomy for vaginal bleeding. She was found at this admission to have a Group 4 squamous cell carcinoma of the cervical stump (pathologic grade 3). Pelvic examination showed an asymmetrical, nodular cervix which showed gross evidence of carcinomatous slough and growth. The lesion measured 3.5 by 3.5 cm., with marked necrosis of the right posterior lip and central portion. The tissue was very friable and bled easily on manipulation. Infiltration of the parametria was found all the way to the pelvic wall on both sides. On May 8, 1947, 11 V.U. of radioactive colloidal gold sol (3.5 ml.) were injected into the left lateral portion of the cancer mass. The right half was not infiltrated to serve as a control. A lead-shielded 2 ml. syringe with a 22-gauge needle was used for the injection in a manner such as employed for local anesthesia. A vaginal pack was inserted and all towels and operative packs were collected for determination of radioactivity lost by leakage. On May 9 the pack was removed and a reading on the Lauritsen electroscope showed that there was no significant (less than 0.5 V.U.) loss of material.

Observation of the site of injection showed no appreciable change until May 15 when two observers noted a slight area of redness on the left as contrasted with the right. Biopsy was taken of the injected and of the control areas. No difference was noted except some increase in mitoses in the untreated area which was not considered significant. On May 10, 13, and 18 measurements by means of the directional differential counting rate meter¹ showed that the radioactive material was well localized in the pelvis and neither the liver nor spleen showed any radioactivity.

On May 21, 44 V.U. of gold sol (13 ml.) were infiltrated into the entire carcinomatous mass. There was a moderate degree of bleeding during the procedure and some of the radioactive material was seen to ooze from the injected site. It was felt that 13 ml. were too large a volume of solution for this size of growth. Vaginal packs removed the following day, as well as packs saved at the time of injection, showed a loss of 24 V.U. of material. On May 23, localization studies with the directional counter showed very small amounts of activity in the hepatic and splenic areas, but most of the radioactivity was demonstrable in the pelvis. Similar findings were noted on May 25. The patient showed no systemic reaction to the radioactive material and was discharged on May 29, 1947, to be followed in the outpatient clinic. The patient died at home on July 13, 1947.

M. B., a 20-year-old unmarried colored woman (gravida iii, abortus iii), while under treatment for secondary syphilis was found to have squamous cell carcinoma of the vagina. On May 22, 1947, the patient was found to have a friable, fungating mass approximately 4 by 6 cm. in the posterior vaginal wall. On May 28, 60 V.U. of radio gold sol were infiltrated. Operative packs, as well as the vaginal pack removed the following day, showed a loss of 57 V.U. of gold,

leaving a negligible amount in the injected mass. However, on May 31 what material was left in the tumor was found to be well localized by means of the directional counter.

On June 5, 1947, 65 V.U. of radio gold sol (4 ml. of solution) were infiltrated into the carcinomatous mass, but seepage collected in the packs showed a loss of 50 V.U., leaving only 15 units in the tissue. There was no systemic reaction to the radioactive material.

It was apparent that the extreme friability of this tissue precluded the retention of the gold sol. The patient was later treated with interstitial implantation of radium.

E. T., a 62-year-old colored woman (gravida i. para i), was found to have a far advanced (group 4) squamous cell carcinoma of the cervix. The patient previously had received deep x-ray and radium therapy with no improvement. There had been several episodes of vaginal bleeding and the patient was admitted on May 11, 1947. Pelvic examination showed marked stenosis of the vaginal canal, obliteration of all vaginal fornices, and replacement of the cervix by nodular, necrotic cancer mass. On May 15, 16 V.U. of gold sol (3 ml. of solution) were infiltrated, and later measurement of the packs showed less than 1 V.U. lost by seepage. Observations with the directional counter on May 17 and 23 showed the radioactive material to be well localized in the pelvis, none being detectable in the hepatic and splenic areas. There was no systemic manifestation attributable to the radioactive material. Daily temperature spikes existing prior to the infiltration showed no change. The patient was discharged on May 28, 1947, to be followed in outpatient clinic. On the tenth day following discharge the patient reported a small hemorrhage of an hour's duration. No significant bleeding occurred in the six weeks following. It was the consensus that there was no significant change in the condition of the carcinomatous mass due to the radioactive material, possibly because of the low dosage employed. The tissue showed the ability to retain the material and it was felt that such local injection of radioactive inert material might offer an approach to the problem of hemostasis in bleeding of far advanced cases of cancer of the cervix.

C. S., a 29-year-old white man, had been under treatment for chronic lymphocytic leukemia for the past year. The patient originally had shown marked hepatosplenomegaly and extensive lymph node enlargement. There were numerous subcutaneous lesions seen on the forehead. These were violaceous in color and were nontender, varying in size from $\frac{1}{2}$ to 2 cm. in diameter. In addition there were a number of pinkish-tan areas of infiltration in the skin of the trunk and of both arms, varying in size from 0.5 to 2.5 cm. and averaging about 1 cm. in diameter. While under intravenous treatment with the radioactive manganese dioxide colloid, there was a diminution in the size of the liver and spleen and a reduction in the white cell count to desired limits as well as good general subjective improvement. Nevertheless the subcutaneous lesions were unaffected over the period of a year and, if anything, were increasing in size and number. On Jan. 2, 1947, 0.15 ml. of colloidal radio gold (0.5 V.U.) was injected into each of the two nodules on the forehead. These nodules were carefully measured, together with two adjacent nodes left uninjected as controls.

Six days later the patient reported no subjective change since the injection except persistent itching in the injected nodes, but no redness, pain, or increased heat. Examination showed no change in the size of the nodes in the horizontal plane. Palpation, however, revealed a definite hollowing out effect in the center of each injected nodule. The nodes which had measured about 2.0 cm. in diameter were depressed and softened in an area measuring about 1.0 cm. in diameter. There was no redness or tenderness. At this time, 0.25 ml. (1.0 V.U.) was injected into each of three new nodules of about 2 cm. diameter on the forehead. The patient complained of a stinging sensation at site of each injection. The next week the three nodes injected were flat, although the outline of each was clearly distinguishable on the surface of the skin and the dimensions in the horizontal plane remained the same. There was a grayish-black discoloration of the skin which measured about 1.0 cm. in diameter immediately overlying the site of each injection. There was no redness, tenderness, swelling, or increased heat in any of these areas. At this time, 2.0 V.U. in 0.3 ml. of solution of colloidal gold were injected into each of the two most posterior nodules on the top of the head. The next week, on examination, the last two nodules injected were entirely flat. There was no pain or tenderness or local tissue reaction at the injected site.

The following week the patient was readmitted to the hospital for blood transfusion and supportive therapy. On this occasion some preliminary attempts at topical application were carried out. The gauze portion of several Band-Aids was soaked with radio gold in the form of the chloride and placed in position over several of the lesions on the upper back. Each Band-Aid contained about 2.0 V.U. of radioactive material. During the ensuing three days a small area of erythema began to develop in each of the treated areas and the patient was aware of a progressive increase in tenderness. On the third day the Band-Aids were removed. At that time each area of erythema measured approximately 3.0 cm. in width. The inflammatory reaction became progressively more marked and at the end of two weeks there was a crust of dry tissue measuring about 2.0 by 3.0 cm., this being surrounded by a ring of erythema of about 2 cm. width. The lesions at this stage were nontender, dry, and clean. During the following week the crusted portions of the lesions underwent desquamation, leaving underneath an area of smooth, pink, normal-appearing skin in which all gross evidence of leucemoid infiltration had disappeared.

On a number of later occasions subcutaneous nodules were infiltrated with colloidal radio gold, usually 1 V.U. of material being injected in each site. The reaction to the radiation was similar to that seen in the earlier trials.

When the patient reported on May 13, 1947, the most striking change was marked increase in the size of the lymphoid masses earlier found in the groin, that on the right measuring 16 by 8 cm. and that on the left 12 by 9 centimeters. Each mass was raised about 2 cm. above the surrounding skin. Both were firm and nontender. Fifteen V.U. of radio colloidal gold in 15 ml. of solution were infiltrated into the mass in the right groin. The transitory burning sensation disappeared after thirty seconds. Eight days later the skin overlying the injected mass showed a dark red discoloration but there was no increased heat or

tenderness in the region. The mass was slightly decreased in size, measuring 14 by 7 cm., and was definitely softer than the uninjected mass on the left. On this date the patient announced that he was leaving town for an indefinite period. When he was readmitted to Vanderbilt Hospital on July 1, 1947, it was found that the "right inguinal mass had diminished greatly in size while that on the left was slightly larger than previously," although the examining house officer did not make any actual measurements. The patient died as a result of hemorrhage into the peritoneum on August 3, 1947.

R. M., a 64-year-old white man with hypernephroma and metastases, first was admitted to Vanderbilt Hospital with the chief complaint of weight loss. The patient had been well until four months previously when he developed postprandial pain relieved by vomiting. There were also anorexia, epigastric fullness, flatulence, abdominal distention, and constipation. There was a weight loss of forty-five pounds in three months. The pain gradually became more severe and the patient weaker. There was an enlarged supraclavicular node as well as enlarged inguinal nodes. Retrograde pyelograms showed filling defects in the calices of the right kidney. A biopsy of the supraclavicular node revealed a hypernephroma metastatic to the node. On Jan. 15, 1947, 45 V.U. of radio colloidal gold diluted in 400 ml. of saline were administered intraperitoneally by slow drip. The patient tolerated the procedure well and complained of no burning or pain at the site of the injection or in the abdomen. During the ensuing five days repeated determinations of the localization of the radioactive material were made with the directional counter. These showed that the material was diffusely spread throughout the cavity and that the majority remained in the peritoneum until radioactive decay was nearly completed. Very little radioactivity could be demonstrated in the liver and none in the spleen, in which sites the gold would be expected to lodge if it were passed via the lymphatics of the diaphragm into the circulation.⁶ At no time did the patient complain of any abdominal pain, nor did repeated examinations reveal any tenderness or spasm. The patient was followed in the outpatient clinic; his course was gradually downhill.

C. B., a 52-year-old white woman, had a seven months' history of hypernephroma. The patient had been treated with radioactive colloidal gold by vein on two previous occasions and that material was well localized in the liver, the spleen, and the remainder of the lymphoid-macrophage system, as shown by use of the directional counter.³ On Feb. 5, 1947, the patient was given 20 V.U. of radioactive gold intraperitoneally in the form of the colloid. Three hours after the injection the patient complained of a severe diffuse abdominal pain. Examination revealed marked tenderness throughout the abdomen. The pain and tenderness gradually disappeared in the next twenty-four hours and the patient was discharged a day later. Repeated surveys with the directional Geiger-Müller counter during the next ten days showed a high degree of activity spread over the entire abdomen.

On a later occasion a metastatic lesion in the right occipitoparietal part of the scalp was directly injected by infiltration with 4 V.U. of colloidal gold. The

lesion was raised, round, and fluctuant and measured 4 cm. in diameter. The patient complained of no pain or burning following the injection, but subsequent radioactivity measurements over the area showed no localization at the site and suggested that the material was promptly removed by the blood stream.

C. S., a 66-year-old white man, was admitted to the hospital on May 14, 1947, with the chief complaint of "swelling of the left eye, trouble seeing and pain." About three months previously he had noted the first swelling on the left side of the nose and of the inner aspect of the left eye. There was also some visual difficulty and diplopia, and frontal headache without dizziness or fainting spells. There was no discharge or bleeding from the left nostril but during the previous month there had been obstruction of this nostril. There was a

Fig. 3.

Fig 3—Squamous cell carcinoma prior to local infiltration.

Fig. 1.

Fig 1.—Squamous cell carcinoma five weeks later.

weight loss of forty pounds in the previous six months. Three weeks prior to admission the patient reported to a physician who removed "a large amount of tissue" from the nostril and referred him to Vanderbilt Hospital.

A year prior to admission the patient had noted a lump in the throat which "cut off my wind" and produced dysphagia and soreness of throat with difficulty in speech. Shortly before this the patient had noted slight hemoptysis characterized by bright red blood on two occasions. On consulting a physician the patient was told he had a tumor of the throat and sent to Nashville where the tumor was biopsied and forty-three x-ray treatments given on successive days. At the end of this period symptoms entirely disappeared. Three months

before admission the patient noted gradual enlargement of lymph nodes on the left side of the neck as well as those in the inguinal region.

Of chief interest on examination was a pterygium on the left medial side of the eye with slight exophthalmos of the left eye. Along the left side of the nose and along the medial aspect of the left eye was a reddish-blue swelling which extended upon the frontal bone about 1.0 cm. above the eyebrow. The left eyeball was displaced laterally and there was moderate tenderness over the swollen area. The left nostril was filled with gray-colored tumor tissue. The tongue and hard palate were hyperemic and smooth, with mild tenderness. Biopsy showed the lesion to be a squamous cell carcinoma. (See Fig. 3.)

On May 14, the skin over the nose was prepared with iodine and alcohol and novocaine infiltrated into the tumor mass. Nine Vanderbilt units of colloidal radio gold were diffusely infiltrated into that part of the tumor overlying the nose. The tumor mass in the left nostril was also infiltrated with novocaine and 4.0 V.U. of gold were injected. The patient complained of a slight burning sensation in the injected area which disappeared in thirty seconds. On May 21, when the patient reported to the clinic, the external mass over the nose and eye was markedly reduced in size. However, two areas at the medial corner of the eye which were not injected were of the same size. The intranasal mass on the left had almost disappeared. A repeat biopsy was taken from the posterior nares. Radio colloidal gold was injected into the area around the medial corner of the left eye, a total of 11 V.U. in about 3.5 ml. of solution being used. An additional 3.5 V.U. were injected into the intranasal tumor on the left. (See Fig. 4.)

DISCUSSION

Direct infiltration of insoluble radioactive colloidal sols of gold is apparently a suitable manner in which to deliver a given amount of radiation to a discrete mass of tissue under certain circumstances.

X-ray can be delivered only from an external source and, except in superficial lesions, must traverse normal tissues. In tumors originating in deep tissues of the body, a considerable thickness of normal tissues must receive extensive irradiation in order to obtain effective dosage in the tumor. In fact, if the lesion is very resistant to irradiation and deeply seated in the body, effective treatment cannot be delivered by x-ray because of extensive damage produced in the intervening normal structures. In the case of injection treatment with radioisotopes, the treatment is from within the tumor toward the normal tissue. Because of the relatively short path of the beta radiations, considerable effect can be produced in the tumor tissue with relatively little damage to the surrounding normal structures. Injection treatment of deep tissue malignancies may eventually prove to be a very valuable agent in the treatment of cancer. Further experimentation with various malignant tumors and possibly other isotopes is necessary to put this form of treatment on a sound clinical basis.

It was somewhat surprising to us that in the two instances in which gold sols were given intraperitoneally the material remained in the peritoneum, since it had been shown that red cells tagged with isotopes when given by this route find their way rapidly into the systemic circulation by way of the

lymphatic system.⁶ It would seem that where generalized diffuse radiation of the peritoneal cavity is desired, as perhaps in abdominal Hodgkin's disease, this might afford a reasonable means of accomplishing it.

In one of the patients with a scalp lesion metastatic to a hypernephroma, injection of the colloidal gold failed to show retention at the site of administration. At autopsy some weeks later it was found that these lesions were traversed by large sinusoids containing blood, and we feel that, in effect, in this case the result was similar to that which would have occurred with intravenous injection.

Most of the subjects treated were far advanced cases in which trial of materials whose correct dosage was unknown was felt justified. In every instance an attempt was made to err on the conservative side and, therefore, we feel that usually the patient was grossly undertreated. However, until more is known concerning the equivalent dosages for various isotopes and until sufficient empirical experience has been obtained to set the correct limits of dosage such a procedure probably will be necessary.

In patient M. B., with carcinoma of the vagina, the character of the tumor mass was such as not to hold injected fluid in a satisfactory manner. Packs removed after instillation and after twenty-four hours showed that practically all of the radioactive colloid had leaked out of this cauliflower-like tissue. Under such conditions it is apparent that the infiltration of gold is highly unsuccessful. We feel that another approach to such problems would be the instillation of $\text{Ag}^{111}\text{NO}_3$, in which the caustic action of the agent is such as to offer hope of tying it to the desired tissue. Under these conditions we might expect that the silver nitrate might undergo reduction by such compounds as ascorbic acid, glutathione, or any other naturally occurring reducing agent; it might react with the chlorides of the tissue fluids precipitating the AgCl ; or it might become bound directly to the tissue proteins. It is well known that in argyria the silver remains in certain sites for extremely long periods of time. Ag^{111} has a pure beta ray spectrum and a half life of seven and one-half days. It is made by transmutation from palladium and therefore has a maximum specific activity eliminating concern of toxic reactions.

The feasibility of use of AgNO_3 by direct infiltration has been briefly tested in experimental animals to determine whether it remained at the site of injection.^{7, 8} These experiments were carried out using $\text{Ag}^{108, 110}$ made by neutron capture in AgNO_3 . The half life is 225 days and therefore not suitable for human studies. The amounts used in such tracer studies were extremely small (about 57 μg AgNO_3) so the conditions were comparable to what might obtain when using the carrier-free Ag^{111} in human therapy.

SUMMARY

1. Under certain conditions it is possible to obtain a high degree of selective radiation of discrete masses of tumor tissue by the direct infiltration of colloidal sols of radioactive gold. In general, the ultramicroscopic particles of gold remain in situ presumably because of their insolubility in body tissue fluids. As a result, a diffuse radiation is possible at any level of tissue ionization desired.

2. Unlike radium implants, it is not necessary to remove the vehicle supplying the source of radiation. Furthermore this material can be infiltrated into tissues which are inaccessible to x-ray and radium therapy, especially should this be feasible in the cases of inoperable tumors found during laparotomy.

3. Cellular structure or vascularity of a tissue may be such as to preclude the retention of solutions injected and the cauterizing properties of AgNO_3 are suggested as an alternative, using the isotope Ag^{111}

We wish to express our appreciation for the cooperation of many members of the resident house staffs in Medicine, Obstetrics, and Surgery, as well as to the members of the Department of Pathology for their valued assistance. We are especially indebted to Dr. John C. Burch, Dr. Herbert Duncan, Dr. G. S. McClellan, Dr. W. David Strayhorn, Jr., and Dr. Albert Weinstein for their cooperation.

METABOLISM OF WOMEN DURING THE REPRODUCTIVE CYCLE

XIV. THE UTILIZATION OF PANTOTHENIC ACID DURING LACTATION

MARGARET N. CORYELL, PH.D., MARY ELLEN HARRIS, B.S., SOL MILLER, M.S.,
HAROLD H. WILLIAMS, PH.D.,* AND IRE G. MACY, PH.D.
DETROIT, MICH.

MANY studies of the metabolism of pantothenic acid have been made with normal and lactating animals, but little information is available concerning its role in human nutrition. Consequently, the Food and Nutrition Board of the National Research Council was not able to include this vitamin in its list of Recommended Dietary Allowances. Since animal experiments have indicated the importance of this vitamin in reproduction^{1,2} and in the growth of young animals,^{3,4} it is likely that it is important similarly in human nutrition. During studies of the utilization of nutrients from food by normal lactating women, pantothenic acid was determined in their food, milk, and urine during the first ten days post partum and during five-day periods at intervals during mature milk production. Other papers have presented the details of the selection of subjects and the organization of the study,⁵ the dietary,⁷ the method of expressing the milk,⁸ and its contents of niacin, pantothenic acid, and biotin,⁹ thiamine,¹⁰ riboflavin,¹¹ ascorbic acid,¹² vitamin A and carotenoids.¹³ The proximate composition,¹⁴ lipid¹⁵ and vitamin¹⁶ contents of human placentas have been published as well as the utilization of ascorbic acid,¹⁷ vitamin A and carotenoids,¹⁸ thiamine,¹⁹ riboflavin,²⁰ and niacin²¹ by the nursing mothers. The utilization of biotin is discussed in a following paper.²² As an adjunct to the study, the amounts of vitamins in the milk and urine of the mothers were determined before and after ten days in which multiple vitamin supplements were added to the diets. The effect of the supplement upon the utilization of vitamin C has been published²³ and its influence upon utilization of other vitamins will be discussed in papers now in preparation.

PROCEDURE

The subjects of the study were multiparas selected during the first trimester of pregnancy on the basis of physical and laboratory examinations and records of having successfully nursed their other children. During all periods of study the women received diets comparable qualitatively but varying in the quantity of all foods, except milk, according to appetite.⁷ Different menus were served each day of the five-day study periods and repeated during each period. Aliquot

From the Research Laboratory, Children's Fund of Michigan.

Presented before the American Institute of Nutrition at its Thirty-First Annual Meeting, Chicago, May 18-22, 1917.

The investigation represented in part by this paper was partially supported by a grant from the Nutrition Foundation Inc. and was made possible by the cooperation of J. P. Pratt, M.D., Chief of the Department of Obstetrics, B. M. Hamil, M.D., Department of Pediatrics, Elizabeth Moran, R.N., Director of Nurses, and Annie Lou Wertz, B.S., Dietitian, all of the Henry Ford Hospital, Detroit, Mich.

Received for publication, Aug. 24, 1917.

*Now professor, Department of Biochemistry, Cornell University, Ithaca, N. Y.

portions of each food as eaten were weighed into a composite which was accumulated for each five-day period of study. Both breasts were completely emptied by manual expression at the usual nursing intervals and samples taken for analysis from the complete twenty-four hour collection of milk. The entire excretion of urine during each twenty-four hours also was obtained for analysis.

Seven women were studied throughout the first ten days post partum. Values were obtained for three other women on their seventh days following delivery. Five of the seven women and four others were studied during seventeen five-day periods while they were producing mature milk.

METHOD OF ANALYSIS

The preparation of the milk samples and the general microbiologic procedure of analysis have been described.⁹

Aliquots (400 Gm.) of ground, mixed food composites were homogenized in a Waring Blendor, transferred quantitatively to a 500 ml. volumetric flask, and diluted to volume. Duplicate 5 ml. aliquots (representing 0.6 to 0.7 Gm. of dry food material) were pipetted into one-liter Erlenmeyer flasks and 400 ml. of distilled water added to each. The flasks were autoclaved for fifteen minutes at 15 pounds pressure. When cool, 1 Gm. of mylase P* in 50 ml. of acetate buffer at pH 4.6 was added to each flask, after which they were incubated at 37° for twenty hours. After heating to 100°, the flasks were cooled, their contents adjusted to a pH of 5.3 to 5.7, diluted to 500 ml., and filtered through Whatman No. 42 paper. The filtrate was diluted to a concentration between 1:100 and 1:200 for assay. The values obtained were corrected for the pantothenate in the enzyme.

Urine was filtered, if necessary, brought to a pH of 6.5 to 7.0, and diluted to a concentration 1:100 and 1:200 for assay.

RESULTS

The twenty-four hour milk and urine volumes and the twenty-four hour excretions in urine and secretions in milk during the first ten days post partum are given in Table I. The average values per day for pantothenic acid intake, secretion in milk, and excretion in urine during all five-day periods of study while the mothers were secreting immature and mature milk are given in Table II.

The average daily pantothenic acid intakes during the two five-day periods of study immediately following delivery ranged from 6.0 to 9.5 mg. (Table I). In general, during the first ten days post partum secretion of the vitamin in milk increased in direct proportion to the increase in volume of milk produced. The influence of nutritional status and physiologic state upon the composition of breast milk is indicated by the high concentrations in the milk of V. S., who ingested multivitamin supplements throughout pregnancy in addition to an excellent diet, and by the low values of C. O., who developed a low-grade infec-

*Mylase P is a diastase preparation obtainable from Wallerstein Laboratories, New York, N. Y., which is more active than clarase in liberating pantothenate and contains less pantothenate.⁹

The first day post partum was variable to the extent of differences in the times at which the women delivered. For subjects delivered after 12 M. the first day began the following morning. The first day for C. O. was 22 hours; for L. F., 23.5 hours. V. G. was delivered eight hours before the beginning of the first day post partum; V. K., seventeen hours; V. L., five hours; J. M., sixteen hours; and V. S., seven hours.

tion near the end of the puerperium. Excretion of pantothenic acid in urine per twenty-four hours was relatively constant for each woman but was not related to urine volume.

The average values per day during all five-day periods (Table II) show the wide variation in milk and urine volumes among the subjects and for the same subject at different times. Although the averages for pantothenate in milk during the two five-day periods immediately post partum portray the large increases in the daily values (Table I) during the first five days, it is interesting that there were only slight differences between the average percentages of intake found in the urine of each woman during the two five-day periods. The greatest difference was an increase from 61 per cent during the first five days to 71 per cent of intake excreted in urine during the second five days by V. S. who had received multivitamin supplements throughout pregnancy. From 70 to 93 per cent of the pantothenic acid intakes of six women during the first five days post partum was accounted for in milk and urine. The range values increased to 94 to 131 per cent for the next five days, with an average increase of 31 per cent. Since the concentration of pantothenate in mature human milk⁹ is quite consistent, the values per day in Table II correspond generally with milk volumes. Excretion in urine showed no relationship with urine volume. For all periods of secretion of mature milk from 49 to 103 per cent of the intake was accounted for in milk and urine, with an average of 77 per cent.

DISCUSSION

The average daily urinary excretions of pantothenate for the various five-day periods are comparable to the average daily figures of 4.94 mg. given by

Spector and co-workers²⁵ for normal adult men under "comfortable conditions," but are somewhat higher than the figure 3.5 mg. per day given by Sarett²⁶ for three normal men on normal diets, or the average values of 3.8, 3.2, and 3.4 mg. found for the normal subjects of Pelezar and Porter,²⁷ Pearson,²⁸ and Wright and Wright,²⁹ respectively. Gardner and associates¹⁰ in a ten-day study, determined the riboflavin, pantothenic acid, and biotin contents of the urine and feces of three healthy young women whose only food other than caramel candy was cow's milk supplemented with a mineral mixture and ascorbic acid. The diet furnished only 6.9 mg. of pantothenic acid daily and the daily urinary excretion of the vitamin averaged 6.0 mg., 87 per cent of the intake. The fecal excretion averaged only 0.41 mg., 6 per cent of intake.

Oldham, Davis, and Roberts,³¹ during studies of twelve young women, determined the pantothenic acid content of seventy-two hour collections of food, urine,

and feces from five to nine of the subjects. During consecutive periods of forty-one to fifty-nine days the women received diets which provided average daily intakes of 2.1, 2.1, 3.5, and 4.3 mg. per day, in that order. During these periods the thiamine and riboflavin intakes also were increased from low levels. Three-day composites for each woman were collected during the last week of the study. At the low level of intake, excretion in both urine and feces was quite consistent, averaging 1.6 and 0.8 mg., 79 and 38 per cent of the intake, respectively. With the increased intake, greater variation occurred among individuals and daily excretions in urine and feces rose. However, the average percentage of intake accounted for in urine decreased with greater intake, lowering the total of intake accounted for from an average of 116 per cent during the first two periods to about 94 per cent during the next two study intervals, which may indicate inadequacy of 2.1 mg. of pantothenate per day to supply the metabolic needs of the women.

With the values given in Table II for nursing mothers, the average daily amounts of pantothenate secreted in milk may be subtracted from the corresponding average daily intakes, with the thesis that only the differences are available for use by the mothers' bodies. These net intakes range from 4.94 to 8.56 mg. for the first five days; from 2.39 to 6.34 mg. for the second five days post partum; and from 4.40 to 7.44 mg. during the periods of mature milk production.

From the data for the first ten days post partum it seems evident that the maternal body can store pantothenic acid or that it is retained in the body for more than twenty-four hours during its metabolism. For the first five days post partum the average net intakes of six women exceeded the respective average daily excretions in urine by 0.46 to 2.78 mg.; during the next five days the average daily urinary excretion by four of the women was greater than the average net intakes. Apparently, physiologic levels of pantothenic acid are maintained in both the milk and urine of nursing mothers regardless of current intake if the women's nutritional status with respect to the vitamins is good. Although some workers believe that some pantothenic acid may be available to the body from fecal synthesis, this has not been proved. Since these nursing mothers, receiving a diet providing ample amounts of the vitamin, excreted over 100 per cent of the net intake in urine it seems unlikely that the feces play a significant role in excretion of pantothenic acid intake.

During the periods of mature milk production the average daily secretions in milk and excretions in urine showed no relationship to each other, to urine volumes, or to average daily intakes. Nor was urinary excretion related to milk volume. Although one woman (M. B.) showed an average of only 49 per cent of her intake in urine and milk, from 63 to 103 per cent of intake appeared in urine and milk during the sixteen experimental periods for eight other women. With intakes averaging 6.0 to 9.5 mg. per day, 32 to 89 per cent appeared in the urine, and the variation in urinary excretion occurred in the same individual as well as among the group. It seems doubtful that any great amount of the pantothenic acid was excreted in the feces.

SUMMARY

Pantothenic acid was determined in five-day composites of food and twenty-four hour collections of the milk and urine of seven multiparas during two five-day periods immediately post partum and of nine nursing mothers during seventeen five-day periods at intervals during the production of mature milk.

The average daily intakes of pantothenic acid ranged from 6.0 to 9.5 milligrams. During the first ten days post partum, daily secretion in milk rose with increasing volumes of milk produced. During the five days immediately following delivery, the intakes of six women were 0.46 to 2.78 mg. in excess of secretion in the milk and excretion in urine; during the next five days the milk and urine of four of the women contained averages of more pantothenic acid than their diets furnished. During the periods of mature milk production, 49 to 103 per cent of intake was found in milk and urine. The urine alone contained 32 to 89 per cent of the average daily intakes during the five-day periods.

METABOLISM OF WOMEN DURING THE REPRODUCTIVE CYCLE

XV. THE UTILIZATION OF BIOTIN DURING LACTATION

MARGARET N. CORYELL, PH.D., MARY ELLEN HARRIS, B.S., SOL MILLER, M.S.,

SPECIFIC biologic effects of biotin and of the lack of it have been demonstrated in various animals and plants, but there is little indication of its basic function in metabolism. Nevertheless, universal occurrence of this vitamin in living cells, its great biologic potency per unit weight, and the knowledge that it plays an extremely important role in the health and growth of animals and plants suggest an equally important function of biotin in the human being. That biotin may be a component of the enzyme systems concerned with the metabolism of pyruvate or lactate has been indicated by the *in vitro* tissue experiments of Pilgrim and co-workers¹ and Summerson and associates.² That it plays a role as a coenzyme in the transfer of carbon dioxide has also been suggested.³ In 1941, West and Woglum⁴ noted, in rats, that some embryo tissues (skin, muscle, lung, and brain) contained two to thirteen times the concentration of biotin found in corresponding adult tissues. More recently, rat experiments by Kennedy and Palmer⁵ have indicated the necessity of biotin for successful gestation, for the birth of viable young, and probably for successful lactation. However, the biotin content of the placenta is singularly low in comparison with the concentration in other organs.⁶

During a comprehensive investigation of the utilization of nutrients from food by normal lactating women, biotin was determined in their food, milk, and urine during the first ten days post partum and during five-day periods at intervals during mature milk production. References are given in a preceding paper⁷ to publications containing the details of the selection of subjects and the organization of the study; the dietary; the method of manually expressing the milk; the concentration of niacin, pantothenic acid, biotin, thiamine, riboflavin, ascorbic acid, vitamin A, and carotene in human milk; the proximate composition, lipid and vitamin contents of human placentas; and the utilization of ascorbic acid, vitamin A and carotenoids, thiamine, riboflavin and niacin by the nursing mothers.

PROCEDURE

The subjects of the study were multiparas selected during the first trimester of pregnancy on the basis of physical and laboratory examinations and records

From the Research Laboratory, Children's Fund of Michigan.

Presented before the American Institute of Nutrition at its Thirty-First Annual Meeting, Chicago, May 18-22, 1947.

The investigation represented in part by this paper was partially supported by a grant from the Nutrition Foundation, Inc., and was made possible by the cooperation of J. F. Pratt, M.D., Chief of the Department of Obstetrics, B. M. Hamb, M.D., Department of Pediatrics, Elizabeth Moran, R.N., Director of Nurses, and Annie Lou Wertz, B.S., Dietitian, all of the Henry Ford Hospital, Detroit, Mich.

Received for publication, Aug. 24, 1947.

*Now professor, Department of Biochemistry, Cornell University, Ithaca, N. Y.

of having successfully nursed their other children. During all periods of study the women received diets comparable qualitatively but varying in the quantity of all foods, except milk, according to appetite. Different menus were served each day of the five-day study periods and repeated during each period. Aliquot portions of each food, as eaten, were weighed into a composite which was accumulated for each five-day period of study. Both breasts were completely emptied by manual expression at the usual nursing intervals and samples were taken for analysis from the complete twenty-four hour collection of milk. The entire excretion of urine during each twenty-four hours also was obtained for analysis.

Seven women were studied throughout the first ten days post partum. One-day values were obtained for five other women on the seventh, eighth, or ninth days following delivery. Five of the seven women and four others were studied during seventeen five-day periods while they were producing mature milk.

METHODS

The general microbiologic procedure employing *Lactobacillus arabinosus* has been described,⁸ including the preparation of food⁹ and milk samples for assay.⁸

Numerous control experiments on the food composites showed that maximum values for biotin, representing the sum of the free and bound biotin contents, were obtained by autoclaving the food aliquots in 2 N H_2SO_4 for three hours at 15 pounds pressure. Stronger or different acids or longer periods of heating did not increase the values obtained. Neutralization with NaOH gave values not significantly different from those obtained after neutralization with $\text{Ba}(\text{OH})_2$ and subsequent removal of the BaSO_4 on filtering. Since the presence of the sulfate ions did not effect the growth of the organism in the assay, NaOH was employed. After neutralization, the autoclaved 5 ml. aliquots were diluted to 500 ml. and filtered through Whatman No. 42 filter paper. The filtrate was diluted further to a concentration suitable for assay, usually 1:200.

The so-called free or loosely bound biotin in the food samples was determined by autoclaving 5 ml. aliquots of the homogenized material with 200 ml. of 0.1 N HCl. When cool, the mixture was brought to pH 5.0 with NaOH, diluted to 250 ml., filtered, and the filtrate diluted to 1:100 or 1:125.

The urine was filtered if necessary and the acetic acid, added as a preservative, neutralized by adjusting the pH to 6.5 to 7.0 before diluting to a concentration of 1:100 to 1:250 for assay.

No attempt was made to differentiate between biotin and its oxygen analogue *dl*-oxybiotin.¹⁰ This vitamin has been shown to have about one-half the activity of *d*-biotin for *L. arabinosus*¹¹ and perhaps one-tenth of the activity of *d*-biotin for rats.¹² In the only available assays of foods, *dl*-oxybiotin was not found in the materials examined, namely organ and muscle tissues and yeast.¹³ Oppel¹⁴ has reported the presence in dog, rabbit, rat, and human urine of a nonavidin-combining biotin, presumably a vitamin.¹⁴ This biotin-like substance was active for his test organism, *Saccharomyces cerevisiae*.¹⁴ It is evidently not oxybiotin, however, since the latter combines with avidin as well as biotin.

RESULTS AND DISCUSSION

The milk and urine volumes per twenty-four hours and the amounts of biotin in the milk and urine of each subject during the first ten days post partum are recorded in Table I.

TABLE I. TWENTY-FOUR HOUR BIOTIN EXCRETION IN URINE AND SECRETION IN MILK DURING FIRST TEN DAYS POST PARTUM

The first day post partum was variable to the extent of differences in the time at which the women delivered. For subjects delivered after 12 M. the first day began the following morning. The first day for C. O. was 22 hours; for L. F., 23.5 hours. V. G. was delivered eight hours before the beginning of the first day of study; V. K., seventeen hours; V. L., five hours; J. M., sixteen hours; and V. S., seven hours.

The values for biotin in milk for the first four or five days following parturition were too low to be reliable. During the second five days both concentration and daily secretion of biotin in milk varied widely among the seven women, ranging from 0.24 μ g per day (0.015 μ g per 100 ml.) to 25.17 μ g per day (2.56 μ g per 100 ml.). Some of the values for the fifth and tenth days show abrupt increases, probably owing to the inclusion of liver, which is rich in biotin, in the menus for the fifth day of each period. Although the subjects show small increases in the biotin content of the milk by the fifth day post partum, they are not nearly so marked as on the tenth day.

Unlike niacin⁹ and pantothenic acid,⁷ biotin excretion in the urine is quite low during the first four days following parturition, increasing several times during the second five days. Increases in urinary excretion on the fifth and tenth days are similar to increased secretions in milk on the days in which liver was included in the diets. Similar changes in the riboflavin content of the milk and urine were noted on those days.¹³ It is noteworthy that the milk of L. F. contained very small amounts of biotin during the first ten days post partum.

*Percentage of intake of total biotin.

†Averages of values for four days.

although in urine she excreted amounts comparable to those of other subjects and by the tenth day was secreting a large volume of milk. That the concentration of biotin in the milk was not lowered by a diluting effect of the high volume secreted is indicated by the values for V. G. who with similar high volume maintained a high concentration of biotin in her milk.

For all five-day periods of study the average daily milk and urine volumes are given in Table II, with the average daily biotin secretions in milk and excretions in urine. For biotin intake both free or loosely bound biotin, as determined after hydrolysis with weak acid for a comparatively short time, and total biotin, the sum of the loosely and firmly bound biotin as determined after hydrolysis with strong acid for long periods of time, are given. It is generally

assumed that the total biotin more nearly represents that available to the animal organism. The biotin in the milk and urine is apparently in the free state, since the values do not increase after hydrolysis with strong acid for long periods of time.

During the periods of mature milk production averages of 2 to 14 per cent of the total biotin intakes were found in the milk secreted during the five-day periods. From 15 to 70 per cent of intake was found in the urine. The diets, which have been described in detail,¹⁶ by analysis provided an average daily intake of 55.8 μg of free biotin and 80.8 μg of total biotin. These values are somewhat higher than those reported for average diets by other investigators. Oppel¹⁷ found daily averages of 30 to 37 μg of total biotin in average diets. Gardner and co-workers¹⁸ reported an average of 33 μg in a moderate-biotin diet which contained no liver or eggs and provided fewer calories and lesser amounts of other vitamins. For diets containing similar amounts of energy and other vitamins, Denko and associates¹⁹ found 37 to 54 μg of biotin, with an average of 44 μg daily. These workers, however, used an enzyme method of extraction²⁰ which in our hands gave the loosely-bound values for biotin in food composites.

The biotin in milk represented a small percentage of the total biotin in the food during the mature milk periods, ranging from 2 to 14 per cent, in comparison with 10 to 34 per cent for pantothenic acid,⁷ 2 to 15 per cent for thiamine,²¹ and 3 to 15 per cent for riboflavin.¹⁵ The average figure for biotin excretion in urine during the periods of mature milk secretion was 47 per cent. With the difficulties of complete extraction of biotin from a food composite and the uncertainty as to whether the values obtained accurately represent the amounts available to the subjects who consume the food, it is not surprising that we found little relationship between average intakes within a narrow range, secretion in milk, and excretion in urine by nursing mothers. Together, milk and urine accounted for 54 per cent of the biotin ingested in the food. With daily intakes of 30 to 37 μg , Oppel¹⁷ found average excretion values of 29 to 54 μg for normal men, about 85 to 159 per cent of the intakes. Denko and co-workers,¹⁹ working with normal young men, found in urine an average of 32 μg or 73 per cent of the average intake of 44 micrograms. Gardner and associates¹⁸ reported that ten normal young women excreted averages of 29, 30, and 167 μg , or 322, 91, and 98 per cent of intakes of 9, 33, and 171 μg per day, respectively. In an earlier study of young women consuming a mineralized milk diet containing 115 μg of biotin daily, Gardner and co-workers²² found an average urinary excretion of 50 μg , 43 per cent of the intake.

Fecal biotin may well be a factor in biotin metabolism, since it has been shown that intestinal synthesis is an important source of biotin in many experimental animals. While fecal analyses do not answer the question as to whether the biotin is unabsorbed intake or the product of intestinal synthesis, or to what extent it has been available to the body, Gardner and co-workers²² found 73 μg , 64 per cent of the intake, in the feces. In another study¹⁹ subjects with intakes of 9, 33, and 171 μg per day excreted 55, 78, and 100 μg in the feces, 611, 236, and 58 per cent, respectively, of the intakes. Oppel¹⁷ found that his subjects on average general diets excreted 86 to 191 μg of fecal biotin per day

Denko and associates¹⁰ reported an average fecal biotin excretion of 133 μg daily, 302 per cent of the intake. These investigators noted that 60 to 100 per cent of the vitamins found in the feces were water-extractable.

The results of experimental work with animals and human beings have established the synthesis of biotin by intestinal bacteria. Moreover, the findings that with low intake the urinary excretion of biotin may be much larger than intake and that a large portion of the fecal vitamin is water-extractable indicate availability of fecal biotin to the body. If further work substantiates this, the wide range of response by individuals in a group might be explained by variation in fecal synthesis.

SUMMARY

Biotin was determined in five-day composites of food and twenty-four hour collections of the milk and urine of seven multiparas during two five-day periods immediately post partum and of nine nursing mothers during seventeen five-day periods at intervals during the production of mature milk.

The values for biotin in milk for the first four days following parturition were too low to be reliable. During the second five days both concentration and daily secretion of biotin in the milk varied widely among the seven women, ranging from 0.24 μg per day (0.015 μg per 100 ml.) to 25.17 μg per day (2.56 μg per 100 ml.). During the periods of mature milk production averages of 2 to 14 per cent of the total biotin intakes (0.9 to 10.8 μg per day) were found in the milk secreted during the five-day periods. From 15 to 70 per cent of the intakes (8 to 54 μg per day) was found in the urine.

A NUTRITION SURVEY OF VIENNESE CIVILIANS UNDER UNITED STATES OCCUPATION, 1945

CHARLES S. DAVIDSON, M.D., C.M.,* MAJOR HAROLD L. WILCKE, SANITARY
CORPS,† CAPTAIN HARRY D. FEIN, MEDICAL CORPS,‡ AND
PRIVATE FIRST CLASS PHILLIP J. REINER§

THE responsibility for providing in United States occupied Germany and Austria an equitable distribution of available food supplies fell to the Army at the end of World War II. In order to meet this responsibility with the most facts, nutrition surveys were planned well in advance and begun in each area as it was occupied.¹ Teams were organized, each composed of a clinical nutritionist, a nutrition officer (Sanitary Corps) experienced in general matters of food and nutrition and in taking dietary histories, and a laboratory technician. We formed one such team and report here the results of a survey of the nutritional status of the civilian population of Vienna in the six bezirks occupied by United States forces. The survey was conducted from August 27 until September 15, 1945. It was on September 1 that the United States Army officially took over the administration of the area assigned to it. Because of this the dietary survey is divided into two sections; the first including bezirks 7, 8, and 9, which adjoin the inner section of the city, and the second, bezirks 17, 18, and 19, which were in the outlying districts. The first part of the survey was made during the Russian occupation of the entire city and the second after these six bezirks were administered by the American Army. Pyke² has reported a similar survey for the British area of Vienna in September, 1945, and the data are quite comparable to those reported here. Following World War I nutrition surveys in Vienna were made under the direction of the American Relief Administration.^{||3, 4}

Consideration will not be given to the previous food intake of the Viennese for two reasons: first, the survey was intended to determine only the food intake at the time the survey was made; and second, reliable figures of food intake during the war were not available. The observations are therefore confined to food intake during the survey itself. It is well known, however, that food was scarce and strictly rationed in Vienna during the war. When the Russian army occupied the city they found that the retreating Germans had left almost no food supplies so that from the end of April until early in June almost no rations at all were issued. During July and August the issue amounted to about 800 calories per day.² In general, the Viennese lost weight on rationed food during the war. Thus the Russians, and soon the other members of the four powers,

Received for publication, September 3, 1947.

*Associate in Medicine and Francis Weld Peabody Fellow, Harvard Medical School; Assistant Physician, Thorndike Memorial Laboratory, Boston City Hospital, Boston, Mass.; formerly Consultant in Nutrition to the Surgeon General of the Army.

†St. Louis, Mo.

§Omaha, Neb.

||We wish to thank the Hoover Library on War, Revolution and Peace, Stanford University, for assistance in obtaining the data from these surveys.

found an undernourished population in Vienna, with almost no food available to ration and with grossly inadequate transportation to bring more food. Further, there was an acute shortage of fuel and housing that complicated immensely the public health problems of the city.

MATERIALS AND METHODS

Food Ration Classification.—At the time of the survey the consumers were divided, according to the Russian method of classification, into five food ration categories: "Heavy Workers; Workers; Employees; Children Under Twelve Years of Age; Others." The "heavy workers" included not only those doing heavy manual labor, but also certain professional people such as physicians, opera singers, and orchestra players. The category "employees" was made up chiefly of white collar workers, and that of "others" of all those not in one of the other categories; that is, housewives, disabled persons, and those too old or otherwise unable to work. The estimated number of individuals falling into each category is shown in the first two columns of Table I.

TABLE I

FOOD RATION CLASSIFICATION	APPROXIMATE POPULATION	TOTAL NUMBER STUDIED	MALE	FEMALE
Heavy workers	10,400	115	105	10
Workers	54,500	540	316	224
Employees	29,600	257	93	164
Children under 14	32,400	548	240	308
Others	138,000	865	86	779
Total	264,900	2,325	840	1,485

Composition of the Population of the Zone of United States Occupation.—The United States Vienna Area Command took over the administration of bezirks 7, 8, 9, 17, 18, and 19 on September 1, 1945. Accurate population figures for this area were difficult to obtain, but the closest approximation was about 260,000. The inhabitants of this area varied from the poorest in the city to some of the most wealthy in the suburban districts of Heiligenstadt and Grinzing. Many professional men and women were included as well as workers. The industries located in the area were mostly small.

Selection of the Sample.—With the cooperation of the Public Health Division of the United States Vienna Area Command, the Viennese public health officials and police located central sites for the examination and called in individuals and families to represent as nearly as possible 1 per cent of the total number of each of the four food ration categories. Table I shows that, with the exception of the category "others," roughly 1 per cent was examined in each category. The number of children was large. In all dealings with the civilian officials an effort was made not to mention that the survey was concerned with nutrition. The survey was organized, they were told, in an effort to understand the general level of health of the people of Vienna under the administration of United States forces. It was usually possible to make sure that those asked to come did so and that those ill at home were noted. It was impossible to visit those not appearing because of illness, but the number of such was small. Indeed, a few of those who came should have been in bed at home. Great care

was taken to insure that no greater proportion of ill and undernourished individuals was examined than was present in the population. It was not always possible to be sure of this but we believe that with the method of selection used this error was largely avoided. Bezirke 7, 8, and 9 included a large proportion of the poor of Vienna, those likely to suffer first. However, the findings were not strikingly different in the other three bezirke in which the people were better able to afford food purchased in the black market. It was well recognized that food was available in the black market in Vienna at this time, but the quantity was so small that it could, and apparently did, make but little difference in the nutritional status of those able to afford it.

In order to include a sufficient number of heavy workers and workers, three factories were investigated: an optical works, a clothing factory, and a paper factory.

Procedure of the Examination.—

Physical Examination: Each individual removed his clothing except for underclothes and stockings, was weighed (kilograms) and the height measured (centimeters). The age, sex, height, weight, and food ration category were entered beside the individual's serial number, as were the findings in the clinical examination. Table III shows the items on physical examination which were specifically sought. In addition, inquiries were made concerning menses (in women between 15 and 44 years of age), weakness, and syncope. The following physical abnormalities were sought but so rarely seen that they were not listed in the table: purpura, loss of vibratory sense in the great toes, muscular tenderness, absence of knee jerks, bossing of epiphyses, beading of ribs, and cranial bossing.

Laboratory Examination: About one of every three of the individuals examined was sent to the laboratory technician and his aides who determined blood hemoglobin and serum proteins by the specific gravity method² included in the mobile field laboratory.

Dietary Survey:

1. Individual dietary history: Slightly over one-third of the individuals reporting for the examination were questioned as to their food intake during the previous twenty-four hours. Models and drawings of food as well as plates and cups were used as aids. The estimated food consumption was calculated by using the composite of the daily results for each class of consumer. In general, the most reliable histories were given by the housewives who prepared the meals for the entire family. In the two factories studied the food served at work for lunch was investigated and the workers themselves were questioned. Reassurance was given that the examiner had no interest in the source of the food (for example, the black market) but only in its quantity. The frequency with which foods appeared which were obtainable only by illicit means was small, corresponding to the estimated size of black market dealings.

2. Rationing and supply of food in Vienna: The food rationing was administered by civilian food authorities and was well organized. Thus it was possible to obtain the ration for each food without any difficulty.

A good insight into the food supplies and the problems of procurement and distribution were obtained by one of us (H. L. W.) who represented the United States in four power conferences on food at the Russian commissariat. It was thus possible to interpret the clinical findings and to some extent to estimate the future nutritional status of the population.

RESULTS

Clinical Examination.—

Physical Measurements: The heights and weights were averaged for the several groups formed from the different age, sex, and food ration categories. These were compared with standards for the United States.^{6, 7} It must be understood clearly that these standards are about 5 kilograms higher than the weight of adult Austrians on a prewar status. Hereafter, the United States standard used will be referred to as the U. S. standard.

Children, taking the 5-, 10-, and 15-year-old groups as examples, averaged not far below the U. S. standard (Table II). This, however, was not true for

TABLE II. AVERAGE HEIGHT AND WEIGHT OF CHILDREN AGES 5, 10, AND 15 YEARS. WEIGHT COMPARED TO U. S. STANDARDS⁶; BOTH HEIGHT AND WEIGHT COMPARED TO SIMILAR MEASUREMENTS, 1920-21^{8, 4}

the adults whose weight reduction below the U. S. standard was more marked. Thus, the averages for adults were below the U. S. standard by from 7 to 12 kilograms.

In addition to comparing averages for adults from 21 to 60 years of age, a distribution curve was constructed showing the frequency of occurrence of overweight and underweight. Each individual's weight was compared with the U. S. standard for age, sex, and height, and the number of kilograms below or above the standard was plotted on the frequency distribution curve (Fig. 1). The mean was -9 kilograms, and the mode, -11 kilograms. The reduction below the U. S. standard for weight becomes more striking when it is recognized that almost half (48 per cent) of those examined were more than 10 kilograms below the U. S. standard.

Fig. 1.

Symptoms and General Appearance: Although not specifically tabulated, many individuals spontaneously complained of weakness, fatigue, and even syncope. It was not unusual to see an ecchymosis or a "black eye" and, upon inquiring, it was frequently found that it had followed a fainting spell due to weakness.

The general appearance of the individuals was not that of extreme under-nutrition but simply of weight loss. Many appeared normal, a few, plump, but most showed evidence of considerable loss of weight and a few showed extreme weight loss. In the latter, posture was often poor, movements were carried out with a characteristic lethargy, and the facial expression was apathetic. Abnormal pigmentation was not seen.

Symptoms and Signs Suggestive of Specific Deficiency States: Severe vitamin deficiencies were not seen. There was no evidence of beri-beri, peripheral neuritis, or of pellagra, and only one individual with classic scurvy was seen. Certain signs that have been described as suggesting specific deficiencies were

recorded as they were seen. The low incidence of most of these signs is given in Table III. Several signs deserve comment.

Goitre, diffuse, nontoxic, was present in from 21 to 42 per cent of the individuals. It is not known whether this incidence is higher in Vienna at this time than before the war.

Distinct papillary atrophy of the tongue was seen in 156 instances. However, in sixty of these the mouth was edentulous so that the significance of the finding in these individuals is open to question. A beefy red or a magenta colored tongue was observed in 404 individuals of whom 102 were edentulous. The combination of papillary atrophy and either beefy red or magenta colored tongue was seen in thirty-two instances, seventeen being edentulous. Other signs suggesting thiamin, riboflavin, or niacin deficiency were almost absent.

Paresthesia and Acrocyanosis: In studying a small group of starved men we described a condition of the extremities, especially the hands, resembling acrocyanosis, which was frequently associated with paresthesia.⁸ The same phenomenon, although with a lower incidence (from 10 to 20 per cent of the adults), was observed in the studies reported here. In the morning, particularly if cold, the hands and feet were cold to the touch and presented a mottled cyanotic appearance. In the warmer part of the day the cyanosis might give way to a mottled reddish flushing, but the hands were usually still cold to the touch. Paresthesia of the hands and feet was associated with acrocyanosis in only forty instances, so that the correlation of the two was not as striking as that found in starved prisoners. The paresthesia was described variously as numbness, tingling, or, often, a burning sensation. These symptoms were most marked in the finger tips and next in the toes; they even extended into the forearms and lower legs.

Edema and Serum Proteins: The serum protein concentration was determined in 859 individuals. The average values for the age and food ration categories are given in Table IV. The individual determinations are plotted as a distribution curve in Fig. 2. It is at once clear that the majority of the serum protein determinations were either normal or slightly reduced and hence the averages were only slightly below normal. Nevertheless, a significant number of individuals were found to have hypoproteinemia. In fact, 28 per cent of the values were 5.5 Gm. per 100 c.c. or below, and over fifty individuals had serum protein concentration between 4.5 and 5.0 Gm. per 100 cubic centimeters. The

TABLE IV. AVERAGE SERUM PROTEIN CONCENTRATION (GM. PER 100 C.C.)

FOOD RATION CLASSIFICATION	AGE	MALE		FEMALE	
		SERUM PROTEIN	NUMBER	SERUM PROTEIN	NUMBER
Heavy workers	19-40	6.8	9	6.3	3
	41-65	6.0	34	6.5	3

	41-65	6.4	89	6.5	53
Employees	19-40	6.3	9	6.3	37
	41-65	6.2	32	6.3	41
Others	19-40	6.6	14	6.5	97
	41-65	6.4	35	6.3	203
Children	1-18	6.3	37	6.5	36

hypoproteinemia, although not general, was present in an undoubtedly larger than normal proportion of the population studied.

Dependent edema was observed in 133 individuals. The data are given in Table V. In eighty-eight of these there was an obvious clinical cause for the edema, such as known or evident cardiac or renal disease, or varicose veins. There were forty-five individuals with edema in whom no clinical cause could be found and who were considered to have "hunger edema." The average age of these two groups was the same, but average weight loss was definitely more in the "hunger edema" group. Likewise the serum proteins, although not excessively low, were definitely lower in the latter group. There were also more signs suggestive of other specific deficiencies in the latter group.

Anemia: Blood hemoglobin concentration was determined in 859 individuals. The average values for the age and food ration categories are given in

Fig. 2.

†Cheilosis, glossitis with atrophy, paresthesia, tongue red or violet in color.

Table VI. The individual determinations are plotted as a distribution curve in Fig. 3. Marked anemia was present in but a very small number. Nevertheless, the average values were definitely below normal. Only in the young male white collar workers was the value above 14 Gm. per 100 cubic centimeters. Thus it appears evident that a mild but definite anemia was present; indeed, a relatively small proportion of the individuals had hemoglobin concentrations of 15.5 Gm. per 100 c.c. or over.

TABLE VI. AVERAGE BLOOD HEMOGLOBIN CONCENTRATION (GM. PER 100 C.C.)

Fig. 3.

Amenorrhea: Absent menses of two months' duration or more, not due to pregnancy, was present in 16 per cent of the women between the ages of 15 and 44. The duration of absence was two to three months in 10 per cent, three to six months in 5 per cent, and more than six months in 1 per cent.

Food Consumption.—

The food consumption of 918 individuals was determined; that of 346 of those from bezirks 7, 8, and 9 is presented in Table VII.

TABLE VII. AVERAGE FOOD CONSUMPTION BY RATION GROUPS, VIENNA, BEZIRKS 7, 8, AND 9, AUGUST 27-31, 1945 (GRAMS PER PERSON PER DAY)

Total	346												

Although meat, fats, and sugar were authorized for issue, there was no meat available and very little fat or sugar. Most families had none of these items. Likewise, there were no eggs available, with the exception of one individual in an outlying bezirk who reported having had one egg; there was almost no cheese. Consequently, the diet consisted principally of bread, or flour, potatoes, and pulses (dried beans or peas) with some fresh vegetables. Contrary to expectations, the vegetable consumption was not higher in the outlying bezirks (except in the case of the children) with the exception of a few cases where pregnant women or nursing mothers were able to obtain small amounts. The significant fact is that all of the protein of the diets of the people in bezirks 7, 8, and 9 were derived from vegetable sources, and this was also true, with a few exceptions, for the other groups surveyed.

It is also to be noted that ration supplements issued for the worker and heavy worker groups were obviously shared with the entire family, since the bread consumption for children was above the ration allowance, while that for the worker categories was below their ration allowance. This is quite evident when flour is considered a part of the bread ration.

The analyses of the food consumed by ration groups, as found in bezirks 7, 8, and 9, are presented in Table VIII.

It is apparent that the diets as consumed were quite deficient in calories, with the possible exception of children up to six years. Eighty-two per cent of the calories were provided from carbohydrates; whereas it is considered that good nutrition requires not more than 60 per cent of the calories provided from carbohydrates, with the balance from fat and protein. In these diets, fat is notably deficient.

The diets were also deficient in calcium, and in vitamin A riboflavin, and niacin. In most cases the vitamin C content is well below the recommended levels, but, with the exception of the diets for the children in bezirks 7, 8, and 9, the deficiency of vitamin C was probably not serious.

DISCUSSION

From the data presented it is clear that the people of Vienna, as seen in the late summer of 1945, were grossly undernourished. This was evidenced by their appearance, weight reduction (48 per cent were more than 10 kilograms under the U. S. standard (Fig. 1), mild anemia, moderate hypoproteinemia, and "hunger edema" in a small but definite number of persons. It is also clear that the food being eaten at the time of the survey was not sufficient to maintain weight and adequate nutrition. Thus, one can from these facts suspect that frank starvation would have ensued at least by midwinter unless more food was provided. Furthermore, it is probable that with the low vitamin content of the diet some avitaminosis might also be expected. Shipments of food began to arrive, however, and it is reported that this continued throughout the winter and spring of 1946 in sufficient quantities to prevent starvation.

Certain of the observations deserve special comment. The low incidence of the signs associated with specific vitamin deficiencies is a remarkable observation and, in general, agrees with most other reports from Europe.^{1, 9} Three factors may help account for this. First, the duration of the very poor diet may not have been long enough to permit the development of signs of deficiency; second, although low in vitamin content, the food did contain some of the B complex, although little C; and third, the metabolic rate was probably significantly reduced. This, as well as the low calorie intake, probably reduced the vitamin requirements.

Loss of weight of adults was by far the most striking finding in the city of Vienna. Nutrition surveys also were made in two smaller cities, Linz (population 250,000) and Enns (population 17,000), by the same group of investigators. In Linz, 22 per cent of the population was more than 10 kilograms in weight under the U. S. standard, in Enns, 18 per cent, as compared with 48 per cent in Vienna. Thus it may be seen that the large city suffered,

as one might expect, much more than the small ones. In a group of German prisoners,⁸ 70 per cent were more than 10 kilograms below the U. S. standard. Here frank starvation was present and the incidence of hunger edema was 24 per cent.

It is a little surprising that the average weight of the children was not greatly below the U. S. standard. A similar survey made in 1920 and reported by the American Relief Administration⁹ reported values for 10- and 15-year-old children that were lower than those given here, both for weight and height (Table II). It seems probable, therefore, that the nutritional status of the children during World War II was somewhat better than during World War I, and reflects the general increase in height and weight in children in many countries following the first war.

The high incidence of weakness, fatigue, and syncope is not surprising considering the extreme weight loss in many of the adults. The poor posture and lethargy have often been observed in severe weight loss.

It is difficult to interpret the occurrence of papillary atrophy and redness of the tongue since these signs occurred largely in edentulous individuals. Incidence of these signs does not necessarily signify a deficiency in vitamin B complex.

An acrocyanotic appearance of the hands, often with paresthesia, was definite but occurred in a much smaller proportion of the population than was observed in a group of starving German prisoners.⁸ This suggests that the phenomenon is related to the degree of undernutrition. Others have described somewhat similar neurological manifestations in undernourished and starved groups and the data have been reviewed recently by Deumy-Brown.¹⁰

The appearance of hunger edema, although in very small incidence, suggests that the nutrition of the general population was at a critical level. The average serum protein concentration was somewhat lower in this group than in those with other forms of edema or in those without edema.

The incidence and duration of amenorrhea in women between the ages of 15 and 44 is probably somewhat increased above that seen in normal individuals in normal times, and is probably related to a number of factors, including undernutrition and stress.

SUMMARY

A survey of the nutritional status of 2,325 Viennese civilians under United States occupation in the summer of 1945 revealed:

1. Marked reduction in weight, especially in adults, below the U. S. standard for height and weight.
2. Commonly observed weakness, easy fatigability, and even syncope; apathetic facial expressions.
3. Surprisingly few signs suggestive of specific vitamin deficiencies.
4. An acrocyanotic appearance of the hands and feet, often associated with paresthesia.
5. Hunger edema in forty-five individuals, although average serum protein concentrations were not far below normal.

6. Average hemoglobin concentrations below normal, although marked anemia was present in but a small number.

Analysis of the average food consumption at the time of the survey showed an intake of from 1,000 to 1,440 calories with about 50 Gm. of protein per day.

FAILURE OF THE ISOLATED PERFUSED MAMMALIAN HEART TO DESTROY RENIN AND ANGIOTONIN

WALTER J. TRAUTMAN, JR., M.D., WILLIAM D. DAVIS, JR., M.D., AND
THOMAS FINDLEY, M.D.
NEW ORLEANS, LA.

IT IS generally assumed that the polypeptide, angiotonin, is the active pressor substance responsible for arteriolar constriction in experimental hypertension and that it is formed by the interaction of the proteolytic enzyme renin on a substrate of plasma globulin. Since the point of pressor activity seems to be directly on the arteriolar muscle, the question of fixation of the pressor material by the effector tissue arises.¹ It is technically difficult to measure fixation by arteriolar muscle, but cardiac muscle is a readily accessible similar material. Consequently, renin and angiotonin were separately perfused through the coronary system of isolated rabbit hearts to determine whether there was any loss of either substance, and saline extracts of perfused and unperfused rabbit hearts were assayed for pressor activity.

Hog renin was prepared from hog kidney powder by the method of Schales.² The first or unpurified fraction of renin was used. This renin, which contained 95 mg. per cent total nitrogen, was relatively stable in the refrigerator and its activity was assayed at four cat units per cubic centimeter.* This renin was diluted to 0.5 and 0.05 cat units per cubic centimeter with Ringer-Loecke's solution. Rabbits were rendered unconscious by a blow on the head and the hearts were removed and washed in physiologic saline solution at a temperature of 37.6° C. The hearts were immediately attached to a modified Langendorff coronary perfusion apparatus and perfused with Ringer-Loecke's solution until they were free from blood, at which time perfusion with renin or angiotonin was begun. Samples of the perfusate as it issued from the venous side were collected at approximately fifteen-minute intervals thereafter until forty-five minutes had elapsed.

The venous perfusate was assayed in cats anesthetized with pentobarbital sodium. Blood pressure changes were read directly from a mercury manometer attached by rubber tubing to a cannulated carotid artery and filled with 4 per cent sodium citrate. The solutions to be assayed were injected into a femoral vein. The higher concentrations of renin were assayed directly as collected from the coronary system, but the more dilute solutions were first converted to angiotonin by the method of Schales, Holden, and Schales.⁴ The angiotonin perfusate was also prepared by this method, beef plasma being used as a source of globulin substrate, and was so diluted with Ringer-Loecke's solution that 1.0 c.c. gave a 20 mm. rise of blood pressure in the assay cats.

From the Research Laboratories of the Alton Ochsner Medical Foundation.

This work was supported by a grant from the Winthrop Chemical Co., Inc., New York, N. Y.

Renin and angiotonin were kindly prepared for us by Otto Schales, D.Sc.

Received for publication, Sept. 29, 1947.

*One cat unit equals the amount of renin which, if injected intravenously in the anesthetized cat, will produce a blood pressure rise of 30 mm. of mercury.

Different rabbit hearts were used for each dilution of renin and angiotonin. All the perfused hearts were frozen in the refrigerator for varying periods. After refrigeration the hearts were cut into small pieces and ground in a mortar. Each minced heart was then shaken with 20 c.c. of physiologic saline solution for thirty minutes, the mixture centrifuged, and the supernatant fluid assayed for pressor activity in the described manner. Unperfused rabbit hearts were treated and assayed in the same fashion.

Equivalent pressor responses were obtained by the concentrated renin solution before and after perfusion through the isolated rabbit heart (Table I, Experiments 2, 3, 4, and 6). Similarly, following conversion of the dilute renin solution to angiotonin no difference in pressor activity could be demonstrated after perfusion (Table I, Experiments 1 and 5). Equivalent pressor responses were also obtained with angiotonin both before and after perfusion (Table II).

Saline extracts of both the perfused and the unperfused rabbit hearts were then injected into assay cats and they produced identical pressor responses. Each kind of extract caused an initial drop in blood pressure of 10 to 15 mm. of mercury followed by a rapid rise of 10 to 15 mm. above its original level which lasted less than two minutes. It is assumed that this pressor response is due to the epinephrine-like compound described by von Euler⁷ and others.

Renin in a concentration of 0.5 cat unit per cubic centimeter, when perfused through the rabbit heart, caused a decrease in the rate and amplitude of ventricular contraction. On the other hand, a solution whose concentration was 0.05 cat unit per cubic centimeter had no demonstrable effect on the heart. It is believed that the toxic effect of the more concentrated renin was due to the toluene preservative or to other foreign material and not to the renin itself, since others⁸ have shown that renin is without effect on the mammalian heart and that toluene in Ringer-Locke's solution is toxic.

Angiotonin, in the concentration used, transiently diminished coronary flow, but a slight augmentation in the rate and amplitude of ventricular contraction was noted. These observations corroborate the work of others.^{5, 6}

CONCLUSIONS

1. Renin and angiotonin may be perfused through the coronary system of the rabbit without loss of pressor activity.

2. Saline extracts of normal rabbit hearts and of rabbit hearts which have been perfused with either renin or angiotonin exhibit slight but equal pressor responses.

POTASSIUM CONTENT OF NORMAL CEREBROSPINAL FLUID

JAMES A. HELMSWORTH, M.D.
CINCINNATI, OHIO

WITH THE TECHNICAL ASSISTANCE OF M. LUCILLE KEEFER

SINCE the investigations of Mestrezat,^{1, 2} reported in 1911 and 1912, the concentration of most of the inorganic elements in normal cerebrospinal fluid has been well known. During the ensuing three decades many workers improved the methods of analysis, adapted them for clinical application, and confirmed the reported concentrations of inorganic elements. The concentrations of the cations sodium, calcium, magnesium, and phosphorus have been well established. The levels of the anions chloride, phosphate, and bicarbonate also can be stated without qualification. The level of the cation potassium, however, has remained more or less in question. For many years the determination of this ion has been of academic interest only, and possibly is even now. For its determination various workers have employed methods derived from chemical reactions which are not ideal for quantitative analysis. Values have been reported after the study of small groups of incompletely described patients. Merritt and Smith³ concluded that, "the potassium content of the cerebrospinal fluid has not been sufficiently investigated."

In Table I the results obtained by workers who have examined normal spinal fluids have been tabulated. In most cases there was no statement of the estimated accuracy of the method employed, nor has it been possible in every case to ascertain the method used. It may be questioned whether the number of determinations made constituted an adequate series for the formation of statistically significant conclusions.

TABLE I. POTASSIUM CONTENT FOUND BY OTHER INVESTIGATORS

INVESTIGATOR	NUMBER OF CASES	RANGE (MG. PER 100 ML.)	AVERAGE (MG. PER 100 ML.)	METHOD OF ANALYSIS
Leulier, Velluz, and Griffon ⁴	20	11 -16	12.3	Modified cobaltinitrite
Pineus and Kramer ⁵	3	12.8-16.6	15.1	Cobaltinitrite
Leipold ⁶	16	10.5-16.9	13.5	Not stated
Merritt and Smith ³	15	11 -15	13.2	Not stated
Honeyman and Zwemer ⁷	10	12 -14.5	13.3	Modified cobaltinitrite
Eisler ⁸	19	13 -13.5	13.2	Cobaltinitrite
Lierle and Sage ⁹	4	not stated	12.8	Cobaltinitrite
Duliere ¹⁰	14	not stated	11.17	Cobaltinitrite
Ballif and Gherseovici ¹¹	not stated	10 -18	not stated	Cobaltinitrite

MATERIAL

The samples of spinal fluid were taken from the lumbar subarachnoid space of patients entirely free from clinical evidence of neurologic disorders. (McCance and Watchorn,¹² in a small series, found that the potassium content of ventricular fluids was slightly less than that

From the Department of Surgery, College of Medicine of the University of Cincinnati, and the Cincinnati General Hospital.

Received for publication, Oct. 10, 1947.

of fluid from the lumbar sac. Unpublished data of our own indicate a difference in the content at the central and at more distal levels in the same patients.) The ages varied widely from the first to the fifth decade. The number of male and female patients was approximately equal. Many of the specimens were obtained at the time of administration of a spinal anesthetic; that is, the fluid was removed before the agent was instilled. The occasion for the anesthesia was an elective operation such as a hernioplasty. Most of these patients had been fasting twelve hours, but there was no apparent disturbance in fluid or electrolyte balance. The remaining specimens were obtained from patients convalescing on surgical wards. Care was taken to use only those who were in satisfactory general health and without fluid or electrolyte imbalance. No fluid was used from any patient who had a positive blood Kahn reaction.

The fluid was collected in chemically clean test tubes with aseptic precautions. It was placed in the refrigerator until the analysis could be begun. Microscopic examination of the fluid was not made in every case. Ballif and Gherseovici¹¹ state that the mixture in vitro of cerebrospinal fluid with the erythrocytes of the same individual did not affect the potassium content of the cerebrospinal fluid, even when the mixture was kept from one to four days. All fluids examined in this study were crystal clear.

As a precaution, all fluids were ashed within forty-eight hours of their removal from the patient. It was believed that delay after this treatment of the sample would not be accompanied by any quantitative alteration of potassium content.

It is beyond the scope of this work to criticize the various methods available for the determination of potassium in biological fluids. Peters and Van Slyke, in addition to other authorities, have indicated that the determination of potassium by converting it to potassium chloroplatinate and subsequently iodoplatinate is a method based on sound principles of quantitative analysis. The Lindo-Gladding procedure¹³ was adapted by Shohl and Bennett¹⁴ and later altered by Consolazio and Talbott.¹⁵ We have employed their methods with few alterations. The changes made, however, seemed of such importance that we have detailed our steps. We have borrowed freely from Shohl and Bennett and from Consolazio and Talbott for the general outline of the analysis.

METHOD

The principle of the method is the precipitation of potassium chloroplatinate in the ash of biologic fluids and its determination by titration. A quantitative determination is made possible by the conversion of potassium chloroplatinate to potassium iodoplatinate on the addition of potassium iodide. The wine color of potassium iodoplatinate varies in intensity depending upon the amount of potassium chloroplatinate reacting with potassium iodide. The rate of development of the color is proportional to the concentration of the potassium iodide. Heat also speeds the development of color. In the presence of acid color development is hastened, but an excess of acid liberates free iodine which will destroy the proportional relation of color development. Sunshine will also liberate iodine.

In the final titration iodoplatinate is reduced in neutral solution with sodium thiosulfate. This reduced salt is lemon colored and serves as a self-indicator. At the end point one drop of the thiosulfate changes the solution's color from reddish to greenish-yellow.

Reagents and Special Equipment.—

50 per cent sulfuric acid.

50 per cent sodium sulfate solution.

20 per cent chloroplatinic acid in N HCl. Made by dissolving 10 Gm. platinum chloride, $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ in N hydrochloric acid and diluting to 50 ml. with N HCl.

Absolute ethyl alcohol saturated with potassium chloroplatinate. The potassium chloroplatinate was prepared by mixing 0.286 Gm. of potassium chloride, 0.5 Gm. of platinum chloride, $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$, and 1 ml. distilled water. These were allowed to stand a short time; the supernatant was then drained off by suction, and the precipitate washed twice with 5 ml. of absolute ethyl alcohol. The precipitate was dried by evaporation and kept in a desiccator. To 500 ml.

absolute alcohol was added the amount of potassium chloroplatinate held on a toothpick end. This was shaken and allowed to stand overnight. Without disturbing the precipitate, the solution was filtered immediately before each use. The unused solution was returned to the bottle containing the excess of potassium chloroplatinate.

2 N (approximately) potassium iodide. This was made each time immediately before use and placed in a brown bottle.

0.1 N sodium thiosulfate. The normality required frequent checking.

0.1 N potassium iodate. This was used to standardize the sodium thiosulfate solution.

10 ml. capacity cone-pointed quartz tubes.

Glass stirring rods, 1 mm. diameter and 200 mm. long.

Muffle furnace.

Microburette with fine capillary tips for delivery.

Capillary suction tips for removal of supernatant without disturbing the precipitate.

PROCEDURE

Each determination was completed in one cone-pointed quartz tube. Two blanks were prepared, each containing one drop 50 per cent sulfuric acid and one drop 50 per cent sodium sulfate. Wherever possible, samples were analyzed in duplicate or triplicate. One milliliter of unknown solution, one drop 50 per cent sulfuric acid, and one drop 50 per cent sodium sulfate were placed in the quartz tube. The tubes were kept in the constant temperature oven at 100 to 105° C. until the solution had evaporated; this process usually required four hours. The tubes were transferred to the sand bath with temperature at 100° C. Placing the tubes in the sand at an angle seemed to result in more even distribution of the heat. The sand bath temperature was slowly raised to 260° C. and maintained for not less than twelve hours. The tubes were transferred to a cold muffle furnace and the temperature slowly raised to 475 to 500° C. This temperature was maintained for four hours and it thoroughly ashed the tube contents, producing a fine white powder. During the process of ashing, the residue tended to creep up the sides of the quartz tubes. Slowing the ashing step controlled this creeping tendency and eliminated the error which would have resulted. The tubes were left in the furnace until cool. Results were better if the determination was continued from this stage without delay.

To each tube was added 0.2 ml. of 20 per cent chloroplatinic acid which dissolved all the ash. Five milliliters of filtered absolute alcohol saturated with potassium chloroplatinate were added; the solution was thoroughly mixed and allowed to stand for thirty minutes. The tubes were centrifuged for five minutes at 2,000 revolutions per minute. The supernatant liquid was removed through a capillary tube by suction. The procedure was carried out with gentle suction because a minute portion of the precipitate floats and does not settle during centrifuging. By keeping the capillary tip well submerged and moving it toward the precipitate in the quartz tube base as siphoning proceeds, all the supernatant fluid can be removed without loss of precipitate.

Five milliliters more of the filtered absolute alcohol were added to each tube and mixed well using the capillary stirring rod which accompanied the tube throughout the determination. All yellow color was washed from the precipitate. Each stirring rod in each quartz tube was rinsed with approximately 0.5 ml. of the alcohol. The tubes were again centrifuged and the supernatant removed by cautious suction. If any yellow color remained in the precipitate, the entire washing process was repeated. Only by washing out all the yellow chloroplatinic acid could an accurate final yield of potassium be obtained.

The tubes were placed in a water bath at 70° C. and slowly brought to boil; boiling was continued until all traces of alcohol were evaporated. After each stirring rod had been returned to its proper tube, the precipitate in each was dissolved in 5 ml. distilled water. To each tube was then added 1 ml. 2 N potassium iodide. The tubes were held in the hot bath a few minutes for full color development and then were placed in an ice bath and kept cold until titration was completed. It was found that the reduced tem-

perature limited the oxidation of the potassium iodoplatinate by atmospheric oxygen, rendering the potassium yield more accurate.

In the absence of direct sunlight, each tube was titrated to a lemon yellow with freshly made 0.01 N sodium thiosulfate. Just before use this was made from the 0.10 N standard sodium thiosulfate reagent. It was found that for accurate results it was necessary to complete the titration within thirty minutes after the addition of the potassium iodide solution.

It is of importance to know the accuracy obtainable by this analysis. Shohl and Bennett,¹⁴ employing the chemical reactions outlined, found that 0.1 mg. could be determined ± 4 per cent, and 0.4 mg., ± 2 per cent. Consolazio and Talbott,¹⁵ modifying Shohl and Bennett's work so that the determinations were carried out in one container (a cone-pointed quartz tube) without transfer, believed their average error to be less than 2 per cent. By statistical analysis of the values obtained from determinations on replicate samples it was shown that in the method employed in this investigation the standard deviation was ± 0.27 mg. per cent. Expressed in per cent the analytical error of the method was 2.75.

RESULTS

The results of the study are summarized in Table II. In analysis of crystal clear samples from sixty-four patients who were without fluid or electrolyte imbalance, detectable signs of organic central nervous system disease, or syphilis, the values were found to range from 8.5 to 11.5 mg. per cent. It is seen in Table I that other workers have found ranges differing somewhat from this. There are two differences which preclude comparison of their results and the results we obtained. The number of analyses completed are not of the same order. In most studies the cobaltinitrite method was employed and it is now accepted that in potassium sodium cobaltinitrite the potassium content may vary.

TABLE II. POTASSIUM CONTENT IN SAMPLES OF SPINAL FLUID FROM SIXTY-FOUR NORMAL HUMAN BEINGS (MG. PER 100 ML.)

8.5	9.3	9.8	10.3
8.7	9.3	9.8	10.3
8.8	9.3	9.8	10.3
8.9	9.4	9.9	10.4
8.9	9.4	9.9	10.4
9.0	9.4	10.0	10.5
9.0	9.5	10.0	10.5
9.0	9.5	10.0	10.5
9.1	9.6	10.0	10.6
9.1	9.6	10.1	10.6
9.1	9.6	10.1	10.7
9.1	9.6	10.1	10.7
9.1	9.6	10.1	10.7
9.2	9.7	10.2	10.9
9.2	9.7	10.2	10.9
9.3	9.8	10.2	11.5

Analysis of the normal values gave a mean of 9.8 mg. per cent. The standard deviation of this value was 1.1 mg. per cent; or expressing the standard deviation of the mean in per cent it was 11.2.

SUMMARY

Brief reference to earlier investigations of the concentration of inorganic constituents of normal spinal fluid has been made. Samples of spinal fluid obtained by lumbar puncture from sixty-four normal people were examined for

potassium content. The steps of the analytical method were detailed; these included the formation of potassium chloroplatinate from the potassium contained in the unknown, the conversion of this salt to potassium iodoplatinate, and its final titration with sodium thiosulfate.

The results obtained from the sixty-four normal subjects were tabulated. The range of potassium was found to be 8.5 to 11.5 per cent. A mean of 9.8 mg. per cent was calculated.

Without the assistance of Dr. Henry Ryder it would have been impossible to complete the statistical analysis of results obtained in the preliminary evaluation of our method and its application to normal spinal fluid. Dr. Charles D. Stevens and Dr. Samuel Rappaport rendered invaluable assistance with many problems which arose as the method of chemical analysis was being perfected.

EFFECTS OF TETRAETHYL AMMONIUM CHLORIDE ON A MIXED TYPE OF HYPERSENSITIVE CAROTID SINUS SYNDROME

ROBERT D. TAYLOR, M.D., LEE C. UNDERWOOD, M.D., AND IRVINE H. PAGE, M.D.
CLEVELAND, OHIO

IT IS now well known that hypersensitive carotid sinus reflexes can cause syncope or convulsive seizures in human beings. Weiss and Baker¹ described three types of cardiovascular response to stimulation of a hypersensitive carotid sinus, all of which may cause loss of consciousness. The first of these occurs without changes in arterial blood pressure or pulse rate. It is accompanied by blanching of the face, which is believed to reflect cerebral vasoconstriction sufficient to cause temporary cerebral hypoxia. The second type, occurring particularly in persons with arteriosclerosis, is accompanied by syncope which is preceded by a marked fall in blood pressure with little or no change in pulse rate. The type of cerebral ischemia thus induced is due to arterial hypotension. These two types of response are thought to result from increased activity of the sympathetic nervous system. The third type, the most common, results from reflex increase of vagal tone. During this form of reaction there is marked slowing of the pulse rate without primary change in arterial pressure. The bradycardia and the accompanying cerebral manifestations can be prevented by adequate dosage of atropine sulfate.

Recently, a patient who exhibited signs and symptoms of increased responsiveness to stimulation of the carotid sinus was referred to the Research Division of Cleveland Clinic Foundation. Because of the present interest in the effects of tetraethyl ammonium ion upon functions of the vegetative nervous system, the effect of the drug was investigated in this syndrome.

CASE REPORT

A 52-year-old white man had noted over a period of months brief episodes of giddiness which followed stooping, sudden turning of the head, and shaving his neck. On one occasion he lost consciousness and had a short convulsive seizure. Examination showed grade 1 retinal arteriolar sclerosis. Arterial blood pressure was 130/80 at the first visit but thereafter averaged 110/70. Pressure applied to the left carotid sinus while the patient was sitting caused bradycardia and reproduced the giddiness. Pressure on the right sinus caused marked slowing of the heart and a brief, generalized, clonic seizure which ended when pressure was removed. Examination showed the blood and urine to be normal. The standard limb leads of the electrocardiogram were normal.

Effects of Carotid Sinus Stimulation on Pulse Rate and Blood Pressure.—Striking bradycardia resulted from pressure applied to either the right or left carotid sinus or to both. In one instance, asystole which was prolonged for 5.4 seconds was recorded in standard limb Lead II of the electrocardiogram (Fig. 1). The blood pressure during stimulation fell from control levels of 110/70 to range from 90/60 to 60/50. The degree of hypotension was dependent on the intensity and duration of pressure and on whether one or both sinuses were stimulated. It was thus regularly possible to reproduce the presenting symptom of giddiness.

From the Research Division of the Cleveland Clinic Foundation.
Received for publication, October 11, 1947.

Fig. 1.—Effects of stimulation of carotid sinuses as observed on Lead II of the electrocardiogram. Arrow indicates time of onset of stimulation. 1, stimulation of the left carotid sinus; 2, stimulation of the right carotid sinus; 3, simultaneous stimulation of the carotid sinuses after stimulation of the carotid sinuses after intravenous injection of 1.3 mg. atropine sulfate; 5, simultaneous stimulation of the carotid sinuses after intravenous injection of 400 mg. tetrathyl ammonium chloride.

Effects of Atropine Sulfate.—After the intravenous injection of 1.3 mg. of atropine sulfate even severe stimulation of the sinuses did not slow the heart rate appreciably (Fig. 1). Although the blood pressure fell from 102/72 to 84/52, no subjective symptoms appeared (Table I). The persistence of a hypotensive response after atropine had prevented bradycardia indicates that the type of hypersensitivity was mixed, that is, of both second and third types of reaction.

TABLE I. EFFECTS OF STIMULATION OF CAROTID SINUSES BEFORE AND AFTER INTRAVENOUS INJECTION OF ATROPINE SULFATE AND OF TETRAETHYL AMMONIUM CHLORIDE

	CONTROL		AFTER INTRAVENOUS INJECTION OF 1.3 MG. ATROPINE SULFATE		AFTER INTRAVENOUS INJECTION OF 400 MG. TETRAETHYL AMMONIUM CHLORIDE	
	BLOOD PRESSURE (MM. HG.)	PULSE (PER MIN.)	BLOOD PRESSURE (MM. HG.)	PULSE (PER MIN.)	BLOOD PRESSURE (MM. HG.)	PULSE (PER MIN.)
Initial	104/70	83	102/70	84	90/60	91
During stimulation of left carotid sinus	98/66	55	88/68	82	90/60	91
During stimulation of right carotid sinus	68/48	(3.2 sec. asystole)	84/54	80	88/50	88
During simultaneous stimulation of both carotid sinuses	60/50	(5.4 sec. asystole)	81/52	70	88/50	85

Effects of Tetraethyl Ammonium Chloride.—Intravenous injection of 400 mg. of tetraethyl ammonium chloride reduced the arterial pressure on an average from 110/70 to 80/50-90/60 on three occasions. There was slight increase in pulse rate (82 to 90) and the only subjective symptoms were slight and transient numbness and tingling. Two to three minutes after administration of the drug, pressure over the carotid bifurcations caused no change in pulse rate, elicited no symptoms, and the blood pressure fell only 5 to 10 mm. systolic and diastolic. The refractory phase persisted for thirty to forty minutes, at the end of which time stimulation induced the phenomena seen in control observations.

Tetraethyl ammonium chloride (400 mg.) was given by intramuscular injection on alternate days for fourteen days. During this time, the symptoms did not recur. However, it was not unusual for several weeks to pass without symptoms when no treatment was being given.

COMMENT

The mechanism by which tetraethyl ammonium ion blocks the passage of impulse over the autonomic nervous system has been studied by Acheson and Moe.^{2, 3} They demonstrated that the drug paralyzes sympathetic and parasympathetic ganglia. Clinical evidences of parasympathetic inhibition were furnished by Lyons and co-workers⁴ who demonstrated gastrointestinal hypomotility and loss of tone of the urinary bladder. Birehall, Taylor, Lowenstein, and Page⁵ attributed the mydriasis and dry mouth which followed intravenous injection of the drug to paralysis of the parasympathetic ganglia of cranial nerves.

In the light of this evidence it is not surprising that tetraethyl ammonium inhibits the increased vagal responsiveness of hypersensitivity of the carotid sinuses. In contrast to atropine, which acts at nerve endings, tetraethyl ammonium blocks transmission at the ganglia. Nevertheless, the ultimate effects of the two drugs on the parasympathetic component of the hypersensitive carotid sinus reflex are similar. This similarity of action does not extend to the sym-

pathetic aspect of the carotid sinus reflex, namely the hypotension. Atropine does not prevent the fall in blood pressure induced by sinus stimulation. Tetraethyl ammonium, by virtue of its blocking both parasympathetic and sympathetic ganglia, prevents both the vagal component of bradycardia and the arterial hypotension.

These observations furnish further clinical evidence of the activity of tetraethyl ammonium on the autonomic nervous system. However, the effects in hypersensitivity of the carotid sinus are transient. Consequently, the drug is not recommended as a substitute for atropine in the management of hypersensitivity of the carotid sinus, characterized by bradycardia.

SUMMARY

A 52-year-old man who had hypersensitive carotid sinus syndrome was observed. Stimulation of the sinuses by pressure caused bradycardia, reduction of blood pressure, giddiness and syncope. The bradycardia was presumably due to increased vagal tone and the fall of arterial pressure to vasodilatation of sympathetic origin. Atropine sulfate, by its ability to inhibit parasympathetic activity, blocked the vagal but had no effect upon the sympathetic component. Tetraethyl ammonium chloride, which paralyzes both parasympathetic and sympathetic ganglia, prevented both responses. This inhibition of the vegetative nervous system by tetraethyl ammonium persisted for only thirty to forty minutes. Because the effect of tetraethyl ammonium, though more complete than that of atropine, is of brief duration, it is not recommended for treatment of hypersensitive carotid sinus syndrome of this type.

We are indebted to Dr. E. C. Vonder Heide, Parke, Davis & Company, Detroit, Mich., for a generous supply of tetraethyl ammonium chloride (Etamon).

LABORATORY METHODS

AN APPARATUS FOR CONTINUOUS RECORDING OF THE VOLUME OF EXPIRED AIR

C. C. SCOTT, M.D., PH.D., AND H. M. WORTH, A.B.

INDIANAPOLIS, IND.

VARIOUS methods are available for recording the respiratory minute volume, most common of which is the collection of expired air in a spirometer or Douglas bag. Obviously there are a number of limitations to such a procedure. We therefore sought an apparatus which would give a continuous record, provide exact information from minute to minute, require practically no attention, and be simply and sturdily constructed. Such a unit with these characteristics has been in use in these laboratories for the past three years. It has been especially valuable in quantitative studies comparing respiratory stimulation¹ and depression² by drugs. Both man and dog have been employed with the same machine. Although not yet tried, respiration of unanesthetized dogs could easily be measured by utilizing an appropriate mask. A very brief description of the method has been given previously.³ Details of construction are herein reported.

APPARATUS

The design of the collecting apparatus is shown in Fig. 1. It consists of two Krogh-type spirometers attached by an overhead cord and pulleys to counter-balance each other. These spirometers are connected to standard one-half inch galvanized pipes to carry the expired air. Four solenoid valves are located in the pipes, two in front of and two behind each spirometer. The solenoids are closed except when activated. The circuit is so arranged that one front valve and the opposite rear solenoid are opened simultaneously, and vice versa. This enables one spirometer to empty while the other is being filled with expired air. Mercury switches are situated above the tanks, contact with which controls the operation of the solenoids. Once contact is made, the mercury switch is inactivated until the tank trips the opposite one. This prevents any possible error, since connections are made to an automatic counter and to a signal magnet for recording on paper. The diagram of the wiring is given in Fig. 2.

In close proximity to the subject or test animal are two valves. Their construction is seen in Fig. 3 and resembles that described by Wright.⁴ Each valve consists of a glass tube surrounded by a small pool of mercury on which rests a lightweight inverted glass cup. One valve allows air to enter for inspiration, while the other transmits expired air to the collecting device. The dead air space is small to prevent undesired effects on normal respiration. All tubing is at least 13 mm. inside diameter to allow air to pass freely. The valves operate easily and are of sufficient size to eliminate points of resistance. We have tried

Received for publication, July 2, 1947.

Fig. 1.—Apparatus for continuously collecting and measuring the volume of expired air.

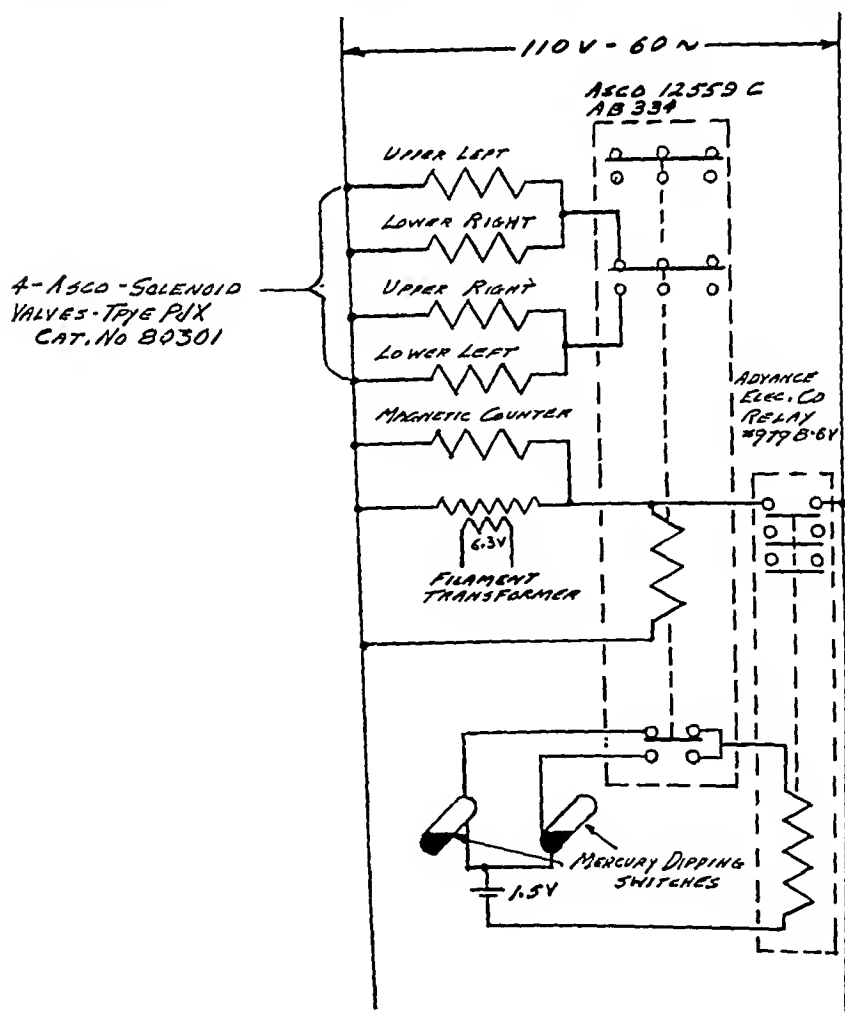

Fig. 2—Wiring diagram of collecting apparatus, switch box, and countersystem

various rubber-flap valves, including those described by Chambers and associates,⁵ but in our experience they tend to leak, particularly during strong respiratory movements. A light bulb with reflector placed close to the expiratory valve provides sufficient heat to prevent condensation of moisture.

The exact resistance to flow of air was measured for different rates and depths of respiration. To do this, a water manometer was connected to a side arm of the tube leading to the subject. For comparison, measurements were made also with a standard basal metabolism machine and a 177-liter Tissot spirometer. The results with the three types of apparatus were quite comparable.

Fig. 3.—Respiration valves which direct expired air to collecting apparatus but prevent re-breathing.

With normal respiration, our machine showed values of -5 mm. water and $+25$ mm. water on inspiration and expiration, respectively. This compared with -7 mm. and $+15$ mm. for the Tissot spirometer, and -3 mm. and $+2$ mm. for the basal metabolism apparatus. When the rate and depth of respiration were augmented, resistance increased greatly with all three devices. Expiratory pressures increased to 70 to 90 mm. water, while there was a decrease of inspiratory pressures to -30 to -60 mm. water. There was no difference between the three methods.

Calibration of the spirometers may be done by a 100 c.c. syringe connected to the animal side of the inspiratory-expiratory valves. By adjusting the

length of the overhead cord, the capacity of the spirometers may be varied. The capacity of the two spirometers is made identical by proper location of the mercury switches. In our experience, 500 c.c. volume changes usually have been employed. Calibration values were determined using different rates of pulsation with the syringe. At rates of 30 to 60 pumps per minute, the error proved to be less than 1 per cent. For instance, ten fillings of each spirometer gave values of 764.5 ± 3.91 c.c. for the left spirometer and 755.5 ± 3.98 c.c. for the right tank, at a rate of 50 pumps per minute. At extremely slow rates of air flow, leakage does occur in the inspiratory-expiratory valve system. This is equally true with rubber-flap valves. However, these rates of air flow have no counterpart in the respiration of human beings or of dogs.

METHOD

Human subjects use a mouthpiece such as supplied with the usual metabolism apparatus. The mouthpiece is connected to the inspiratory-expiratory valves which in turn are attached to the spirometers. About five minutes are usually required for the subject or patient to become accustomed to the procedure and for respiration to stabilize. Subsequently, a recording or measuring period of ten minutes is sufficient, but a much longer duration is easily tolerated. This procedure may be repeated at regular intervals to test the prolonged action of such drugs as morphine.

In our experience, sodium phenobarbital is a good anesthetic for respiratory studies in dogs. Owing to its long action, respiration will remain unchanged for hours. This is a distinct advantage in measuring the stimulating or depressing action of any drug.

This apparatus should be easily adaptable to other types of respiratory studies. In case inspired gases other than ordinary air were needed, it would be necessary only to connect a supply of the desired gas or mixture of gases to the tube on the inspiratory valve.

SUMMARY

An apparatus is described which continuously records the volume of expired air. Essentially it consists of two spirometers with appropriate valves. While one spirometer fills with expired air, the other tank empties. At each filling, registration is made by both a signal magnet and an automatic counter.

A MICROMETHOD FOR THE DETERMINATION OF THE ALBUMIN-GLOBULIN RATIO IN GUINEA PIG SERUM

E. E. ECKER, PH.D., AND B. LIKOVER, B.A.
CLEVELAND, OHIO

WHILE conducting certain studies on the sera of guinea pigs it was found desirable to determine the albumin-globulin ratio of these sera. Since the methods employed generally require the withdrawal by cardiac puncture of considerable amounts of blood, a micromethod was developed requiring only one-tenth of a milliliter of serum. The blood was obtained by making an incision perpendicular to and across the marginal vein of the ear and gently expressing the blood into a capillary tube. The technique of bleeding is described by Ecker, Hiatt, and Barr.¹

METHODS

The micromethod is based on the methanol precipitation of the globulins in human serum as employed by Pillemer and Hutchinson.² The conditions were standardized in such a manner that the results obtained by the micromethanol precipitation technique agreed with those secured by the electrophoretic analysis of the same sera.

It was noted that at 0 to -5° C. the serum albumin remained soluble at a concentration of 42.5 per cent methanol, pH range of 5.3 to 5.5 (before addition of methanol), and ionic strength of 0.015. Under these conditions all the globulins were precipitated.

TABLE I. COMPARISON OF THE ALBUMIN-GLOBULIN RATIOS OF GUINEA PIG SERA BY ELECTROPHORETIC ANALYSIS AND BY METHANOL PRECIPITATION

	GUINEA PIG*									
	1	2	3	4	5	6	7	8	9	10
Electrophoresis										
Gm. albumin per 100 c.c.	3.15	2.64	2.86	2.96	3.42	3.24	2.39	1.98	2.36	2.58
Gm. globulin per 100 c.c.	3.02	2.95	2.70	3.11	3.19	2.60	2.72	2.47	2.98	1.87
Albumin-globulin ratio	1.04	.89	1.06	.95	1.07	1.25	.88	.80	.79	1.38
A/G Micromethod										
Gm. albumin per 100 c.c.	3.17	2.62	2.69	2.89	3.35	3.25	2.36	1.90	2.44	2.49
Gm. globulin per 100 c.c.	3.00	2.97	2.87	3.18	3.26	2.59	2.75	2.55	2.90	1.96
Albumin-globulin ratio	1.05	.88	.94	.91	1.03	1.26	.86	.74	.84	1.27
Per cent deviation of AG ratio	.96	1.12	11.32	4.21	3.73	.80	2.27	7.50	6.34	7.60
Average deviation, 4.6%										

*Guinea pigs 1 through 6, normal guinea pigs; 7 and 8, bled by cardiac puncture for three successive days before getting serum sample; 9, post-partum guinea pig; 10, 4-week-old guinea pig.

From the Institute of Pathology of Western Reserve University and the University Hospitals.

Aided by a grant from the Commonwealth Fund.

Received for publication, Aug. 4, 1947.

A comparison of the albumin-globulin ratios obtained electrophoretically and by the micromethod is found in Table I.

The results obtained indicate that the two methods agree closely, the average deviation being less than 5 per cent.

As an additional proof of the value of the micromethod, the globulins of 8 ml. of pooled guinea pig sera were precipitated at the same dilution and under the same conditions as employed in the microtechnique. The globulin precipitate was washed once and dissolved in a veronal buffer (pH, 8.6; μ , 0.1) for electrophoretic analysis. The supernatant albumin was lyophilized to dryness and also dissolved in veronal buffer.

The patterns of the two samples showed that the albumin fraction contained less than 2 per cent globulins, while the globulin fraction contained 7.7 per cent of albumin, most of which can be attributed to occlusion.

MATERIALS

Methanol Reagent.—Chemically pure methanol, 607 ml., are added with mixing to 393 ml. of distilled water. This mixture is cooled to 0° C. and made up to 1 liter with cold methanol.

Acetate Buffer (pH, 5.4; μ , 0.05).—Sodium acetate $3\text{H}_2\text{O}$, 6.8 Gm., and 1 N acetic acid, 10.6 ml., are diluted to 1 liter with distilled water. The pH of the solution should be between 5.3 and 5.5.

PROCEDURE

1. Place 2.9 ml. of acetate buffer in a 5 ml. volumetric flask and to this buffer add 0.1 ml. of the test serum with a volumetric pipette.

2. With a volumetric pipette remove 2 ml. of this 1:30 serum and transfer it to a 15 ml. conical centrifuge tube. Blow the small amount remaining in the tip of the pipette back into the 5 ml. flask so that exactly 1 ml. is left.

3. Add 1 ml. of the acetate buffer to the centrifuge tube and fill the volumetric flask to the 5 ml. mark with the buffer.

4. Cool the buffered serum in the centrifuge tube to 1° C. Add 7 ml. of the methanol reagent cooled to 0 to -5° C. Stir well, stopper, and allow to stand for thirty minutes at 0 to -5° C. During this period the globulins will precipitate, leaving the albumin in solution. The suspension is then centrifuged for thirty minutes at 2,000 revolutions per minute in a refrigerated centrifuge at 0 to -5° C.

5. Withdraw a 4 ml. aliquot sample of the supernatant with a volumetric pipette, transfer it to a digestion flask, and determine the nitrogen content.

6. A 4 ml. aliquot sample from the 5 ml. volumetric flask is then withdrawn and transferred to a digestion flask for a determination of its nitrogen content. From this analysis the total serum protein content is obtained. Nitrogen determinations are made according to the Pregl and Grant² technique with two blanks, one of which is made up of the same proportions as the albumin supernatant (3 parts buffer and 7 parts methanol), and the other consisting of 4 ml. of buffer.

CALCULATIONS

$15/4 \times \text{mg. N in supernate} = \text{Gm. albumin per 100 ml. of serum}$
 $15/4 \times \text{mg. N in total protein sample} = \text{Gm. of total protein per 100 ml. of serum}$

$$\frac{\text{Gm. albumin N per 100 ml. of serum}}{\text{Gm. total protein N per 100 ml. of serum}} = \text{Per cent albumin}$$

$\text{Gm. total protein N per 100 ml. of serum} - \text{Gm. albumin N per 100 ml. of serum} = \text{Gm. globulin N per 100 ml. of serum}$
 $100 \text{ per cent} - \text{Per cent albumin} = \text{Per cent globulin}$

$$\frac{\text{Per cent albumin}}{\text{Per cent globulin}} = \text{Albumin-globulin ratio.}$$

SUMMARY

A method is presented which gives the albumin-globulin ratio in as small a quantity as 0.1 ml. of guinea pig serum. Values obtained by this technique compare favorably with those obtained electrophoretically. The conditions found here apply to guinea pig serum. Extension of the method to the sera of man and of other animals requires a readjustment of the conditions for precipitation.

SCHLESINGER'S TEST FOR UROBILIN IN THE PRESENCE OF RIBOFLAVIN AND OTHER FLUORESCENT COMPOUNDS

HANS N. NAUMANN, M.D.
TAUTON, MASS.

IN THE past, urinary fluorescence has been noted occasionally following the ingestion of acriflavine,³ eosin,¹³ and fluorescein.⁵ With the recent widespread use of vitamin preparations green urinary fluorescence due to riboflavin is often found which interferes with the green fluorescence of urobilin produced in Schlesinger's zinc acetate-alcohol test. Such interference may be troublesome in cases of hepatic diseases in which urobilinuria is an important sign and, at the same time, vitamin B medication is an accepted treatment.

Ehrlich's test for urobilinogen, as recommended by Watson,²⁰⁻²² is generally preferred and is not influenced by fluorescent compounds with the exception of acriflavine.¹⁵ The orange color or precipitate of the latter can be prevented by the addition of sodium acetate, according to Watson. Schlesinger's test, however, still has its merits, namely, in cases of old urine specimens where urobilinogen has been oxidized to urobilin, in determinations on urine of jaundiced patients where biliverdin formed by the hydrochloric acid of Ehrlich's reagent may mask the red urobilinogen reaction, in cases of albuminuria where protein interferes with Ehrlich's test,¹⁶ and whenever a confirmation of Ehrlich's test is desired.

The following methods allow the performance of Schlesinger's test in the presence of riboflavin and other dyes exhibiting green fluorescence which may occur in urine, and tests for their identification are given.

TECHNIQUE OF PROCEDURES

*I. Schlesinger's Test in the Presence of Riboflavin**

Principle.—Urobilin is extracted with chloroform in which riboflavin is insoluble and the chloroform extract treated with zinc acetate and alcohol.

Method.—Ten cubic centimeters of urine, 10 c.c. of chloroform, 10 drops of concentrated HCl, and 2 drops of tincture of iodine are shaken and centrifuged. The chloroform layer is drawn off, mixed with half its volume of alcohol, about 0.2 Gm. of zinc acetate, and 1 drop of concentrated NH₄OH, and filtered. The filtrate is viewed through the height of the fluid column with strong side light against a background of black velvet for the presence of green fluorescence.

Comment.—The extraction of urobilin is not complete. Bilirubin is partially extracted and may exhibit a reddish fluorescence as first observed by Auché² and later investigated by Dhéré.⁴ This red fluorescence, however, is generally too weak to interfere.

From the Department of Pathology, Taunton State Hospital.

Received for publication, Aug. 20, 1917.

*The products used were: riboflavin, Harris Laboratories, St. Louis, Mo.; acriflavine, Abbott Laboratories, North Chicago, Ill.; fluorescein, Merck & Co., Inc., Rahway, N. J.; eosin and erythrosin, National Aniline and Chemical Co., New York, N. Y.; mercurochrome, Hynson, Westcott & Dunning, Inc., Baltimore, Md.

II. Schlesinger's Test in the Presence of Acriflavine*

Principle.—Acriflavine is rendered insoluble in chloroform by treatment with NaNO_2 in acid solution, resulting in a purple color reaction.

Method.—Ten cubic centimeters of urine are treated with 10 drops of concentrated HCl and 10 drops of 5 per cent NaNO_2 and the test completed as under I.

Comment.—An investigation into the nature of the purple color reaction which may be due to formation of a nitroso compound or to simple oxidation has not been attempted.

III. Schlesinger's Test in the Presence of Fluorescein, Eosin, Erythrosin, and Mercurochrome*

Principle.—Urinary pigments are adsorbed on cotton in a Tweed column and urobilin is eluted with ammonia and alcohol.

Method.—A glass tube 20 by 1.5 cm. with tapered end (the lower end of a 100 c.c. burette is suitable) is stuffed moderately tightly with absorbent cotton to a height of 18 cm.; 10 c.c. of urine mixed with 10 drops of concentrated HCl and 20 drops of bromine water are poured on the column and allowed to soak into the cotton, followed by 1 c.c. of concentrated NH_4OH and 6 c.c. of 95 per cent alcohol. Two cubic centimeters of filtrate are slowly collected; 10 c.c. of alcohol and 3 drops of concentrated NH_4OH are added. Half of this mixture is filtered without and the other half filtered with the addition of about 0.3 Gm. zinc acetate. Fluorescence of the latter filtrate indicates the presence of urobilin, while the former serves as a control and may show a faint fluorescence due to fluorescein derivatives which were not completely retained by the cotton.

Comment.—The procedure is based on Arata's test¹ for the artificial coloring of food. Since urobilin is partly adsorbed¹⁰ and incompletely eluted the test is not very sensitive and a weak fluorescence is evidence of increased urobilin. Bilirubin is retained in the cotton and thus separated from urobilin. Eosin is best adsorbed and fluorescein least, necessitating its conversion to eosin by bromine prior to adsorption. In order to insure sufficient retention of these dyes the pinkish or orange color ring appearing on elution should not move further than about two-thirds down the column.

IV. Spectroscopic Test of Urobilin and Fluorescent Dyes in Urine

SPECTROSCOPIC DETECTION OF UROBILIN IN THE PRESENCE OF FLUORESCENT DYES.—

Principle.—A urinary chloroform extract free of flavins is treated with zinc acetate, alcohol, and acid whereby the spectrum of acid urobilin is produced while fluorescein derivatives do not give any absorption in acid solution.

Method.—The procedure is the same as under I. Five cubic centimeters of the final solution are acidified with 3 drops of concentrated HCl , filtered, and examined in a suitable layer with a wave length spectroscopet for the absorption of acid urobilin at 504 to 478 millimicrons.

See footnote on p. 1503.

†The grating spectroscopet of Schmidt and Haensch, Berlin, was used.

Comment.—In the presenee of much urobilin the usual Schlesinger filtrate may be used, but the absorption band is not so sharply defined. The spectroscopic test is far less sensitive than the fluoreseence test.

SPECTROSCOPIC DETECTION OF FLUORESCENT DYES IN THE PRESENCE OF UROBILIN.—

Principle.—The urine is extracted with amyl alcohol, diluted with 95 per cent alcohol, and rendered alkaline. The comparatively weak absorption band of urobilin does not interfere as a rule.

Method.—Ten cubic centimeters of urine (or a larger volume) acidified with 4 drops of concentrated HCl are shaken with 5 cubic centimeter of amyl alcohol and centrifuged. The amyl alcohol is drawn off, mixed with an equal volume of 95 per cent alcohol and 3 drops of concentrated NH_4OH ; and diluted with more alcohol if necessary. The solution is examined with the spectroscope for the absorption bands given in Table I.

TABLE I. SCHEME FOR PRELIMINARY IDENTIFICATION OF FLUORESCENT DYES IN URINE

COMPOUNDS	URINE OF YELLOWISH COLOR; STRONG YELLOW-GREEN FLUORESCENCE IN UV LIGHT	URINE OF PINKISH COLOR; DULL MAUVE FLUORESCENCE IN UV LIGHT	REMARKS
Riboflavin	Not extractable with ether or chloroform; spectroscopic: darkening of right side of spectrum up to about 500 $\text{m}\mu$ Purple color reaction with NaNO_2 and acid; spectroscopic: similar to riboflavin Conversion to eosin with bromine and acid; spectroscopic: 512 – 491 $\text{m}\mu$		
Aceriflavine			
Fluorescein			
Eosin		Adsorption on cotton; spectroscopic: 537–521 $\text{m}\mu$	Filtering acidified urine through cotton in Gooch crucible
Mercurochrome		Test for mercury; spectroscopic: 534–511 $\text{m}\mu$	Gottler's test ⁶ in urine, concentrated if necessary. ⁷
Erythrosin		Weak fluorescence; spectroscopic: 528–502 $\text{m}\mu$	Identification by absorption curve or biologic test. ³

Comment.—The method of Discombe⁵ may be used but it requires larger amounts of urine. Urobilin up to concentrations of 200 mg. per cent in terms of urobilinogen did not interfere when the dye concentrations were 1 mg. per cent. As noted from Table I, the absorption bands of eosin, mercurochrome, and erythrosin are very similar and it is doubtful whether spectroscopy alone will be sufficiently accurate for their differentiation.

DISCUSSION

The excretion of riboflavin after vitamin B medication depends on the dose of riboflavin, which may vary from 5 to 50 mg. per day,¹¹ on urinary concentration, and on the excretory capacity of the kidneys. The fluoreseence

in concentrated specimens may be noticed easily under ordinary lighting conditions or may be so weak that it can be seen only when the filtered urine is examined with strong side light. But even weak concentrations are revealed instantly in filtered ultraviolet light by the brilliant yellow-green fluorescence which is superimposed on the gray-white fluorescence of normal urine.¹³ Since treatment with vitamin B complex is advocated also in psychoses,¹⁹ fluorescent urines are frequently found in patients in mental institutions.

There are only three reports on urinary fluorescence due to compounds other than riboflavin. Goldschmidt³ found fluorescence caused by acriflavine (trypanflavin) which is listed in *The Dispensatory of the United States of America*²³ and Gutman's *Modern Drug Encyclopedia and Therapeutic Index*²⁴ as an external and internal disinfectant and, at one time, was used as a gall bladder antiseptic. Schumm¹⁵ observed a fluorescent urine due to eosin, the source of which could not be determined. Discombe⁵ found fluorescein in urine after ingestion of a proprietary drug. As fluorescein is used increasingly as a diagnostic aid, for example for the determination of the circulation time,¹⁴ for the examination of the adequacy of peripheral blood vessels,¹² and for visualizing gastric ulcers during gastroscopy,¹⁷ one may expect to find fluorescein in urine more often.

The author noted several cases of urinary fluorescence due to acriflavine following medication, two cases due to mercurochrome subsequent to bladder irrigation, and three cases due to fluorescein of undetermined origin. Recently, an eosinlike dye was found in urine following the swallowing of a lipstick by a mental patient. According to information received from the Food and Drug Administration* this dye most probably was rhodamine B, commonly used for coloring lipsticks. Another fluorescent urine on extraction yielded a dye which showed some characteristics of erythrosin but could not be identified definitely due to insufficient material. Erythrosin, the only red coal tar dye permitted for coloring food, is presumably ingested frequently but, due to its weak fluorescence and the small quantities excreted, has probably escaped notice.

The scant reports in the literature do not necessarily indicate that urinary fluorescence is not being encountered from time to time by laboratory workers and, if present in Schlesinger filtrates, it may be wrongly interpreted as urobilinuria. For such occasions it was thought helpful to refer to Table I which presents a simple scheme for the preliminary identification of fluorescent dyes which may occur in urine.

SUMMARY

1. A modified Schlesinger test has been described allowing the separation of urobilin from riboflavin whose green fluorescence in urine following vitamin B medication interferes with that of the urobilin-zinc compound.

2. Modifications of Schlesinger's test in the presence of fluorescent dyes occasionally present in urine, such as acriflavine and fluorescein and derivatives, have been described.

3. Tests for identification of fluorescent dyes in urine have been given.

*I wish to express my thanks to G. Robert Clark, Acting Chief, Cosmetic Division, Food and Drug Administration, for his helpful information.

PROCEEDINGS OF THE CENTRAL SOCIETY FOR CLINICAL RESEARCH

Twentieth Annual Meeting
Chicago, Ill., Oct. 31 and Nov. 1, 1947

TO BE READ BY TITLE—CONCLUDED

51. CONTINUOUS OBSERVATIONS OF THE ARTERIAL OXYGEN SATURATION AT REST AND DURING EXERCISE IN CONGENITAL HEART DISEASE

GEORGE E. MONTGOMERY, JR., M.D. (BY INVITATION), EARL H. WOOD, M.D. (BY INVITATION), HOWARD B. BURCHELL, M.D., THOMAS J. DRY, M.D., ROBERT L. PARKER, M.D. (BY INVITATION), AND H. FREDERIC HELMHOLZ, JR., M.D., ROCHESTER, MINN.

Analysis of arterial samples from twenty resting persons with congenital heart disease has been used as a reference point for continuous measurements of the arterial oxygen saturation with the Milliken compensated circuit oximeter during exercise and other procedures. Nineteen normal volunteers were studied as controls. Observations have been made while the individuals breathed pure oxygen, with and without positive pressure up to four inches (10.2 cm.) of water, while they stood upright, and while they walked on a power-driven treadmill at 1.7 miles per hour.

In normal persons at rest, oximeter readings indicated that the arterial saturation was increased by from 1 to 5 percentage points (mean, 2.7) in an average time of 1.3 minutes when pure oxygen was breathed. Addition of positive pressure to the oxygen supply caused no further change in the oximeter reading.

In resting patients with cyanotic types of congenital heart disease the arterial oxygen saturation averaged 71 per cent, ranging from 45 to 91 per cent saturation. Oximeter readings were increased from 2.0 to 16.5 percentage points (mean, 6.2) in an average time of 3.0 minutes when these patients breathed pure oxygen. When the oxygen was given with positive pressure, oximeter readings increased, on the average, an additional 1.6 percentage points.

The normal group showed no significant change in their arterial oxygen saturation when they assumed the upright position or when they exercised by walking on a horizontal treadmill at 1.7 miles per hour for five minutes. The oximeter readings of persons with cyanotic types of congenital cardiac defects decreased, on the average, 2.4 percentage points when they stood upright, and decreases ranging from 3.5 to 19.0 percentage points (mean, 10.9) occurred when they walked on the treadmill at 1.7 miles per hour for an average time of 3.5 minutes.

Simultaneous arterial samples and oximeter readings obtained both at rest and during exercise in a smaller series of patients indicated that the saturation

changes recorded by the oximeter were less than the changes found by the van Slyke analysis of arterial blood. Nevertheless, use of the oximeter in these tests has proved a valuable objective adjunct in assessing the degree of dysfunction in such patients both before and after surgical corrective procedures have been attempted.

52. A TWELVE-YEAR STUDY OF A PARTICULAR GROUP OF HYPERTENSIVE PATIENTS PRE- AND POSTSYMPATHECTOMY WITH REFERENCE TO RENAL PATHOLOGY

M. H. BARKER, M.D., H. A. LINDBERG, M.D., AND N. V. TREGER, M.D.
(BY INVITATION), CHICAGO, ILL.

In the past twelve years twenty-five cases of essential hypertension were studied jointly by the medical and surgical services of a university hospital. A part of this study is reported in this paper, the correlation of vasomotor tests with the anatomic changes found in renal biopsies (six) or at autopsy (four).

Selection of a particular group of patients for consideration of surgical therapy was made in the hope that eventually the surgical treatment of hypertension might be completely and properly evaluated. These patients were those whose course was rapidly progressive despite vigorous, nonsurgical therapy. The immediate prognosis in all instances was considered to be good; the ultimate prognosis, however, was always poor.

The same surgeon (Dr. Loyal Davis) performed the several types of sympathectomy, adding thereby to the uniformity of the results.

During the period of this study numerous tests for vasomotor lability were introduced as an aid in the selection of cases suitable for sympathectomy. The following tests were employed: (1) resting blood pressure, (2) sodium amytal test, (3) cold pressor test, (4) continuous caudal anesthesia, (5) carbon dioxide sensitivity, (6) reaction to tetraethylammonium chloride, and (7) a new test, the vertavis test. Most were repeated after sympathectomy and some were observed in the interval between operations in cases where a thoracolumbar sympathectomy was performed. These tests have been compared with the anatomic changes found and the clinical course to date. During the period of observation, none of the tests showed a high degree of correlation with reference to these two factors. Some of the patients reported on here have been followed continuously for twelve years after sympathectomy. Proper case selection for the surgical treatment of hypertension, we feel, is still most difficult, if not impossible, at this time. It is our impression that patients not responding to thiocyanate therapy are unsuitable for sympathectomy.

53. THE EFFECTS OF A DIET OF RICE AND FRUIT JUICES UPON THE BLOOD PRESSURE OF HYPERSENSITIVE INDIVIDUALS*

HENRY A. SCHROEDER, M.D., PALMER H. FUTCHER, M.D., AND
MELVIN L. GOLDMAN, M.D., ST. LOUIS, MO.

(INTRODUCED BY EDWARD H. REINHARD, M.D., ST. LOUIS, MO.)

Attempts were made to evaluate the use of a diet composed of rice, fruit juices, and vitamin supplements in the treatment of arterial hypertension, since others have reported beneficial effects from this and other low salt diets.

*This study was supported by a grant-in-aid from the United States Public Health Service.

Six patients, five of whom showed essentially normal renal function, were studied extensively, control periods of approximately one month in the hospital being observed. These patients suffered from arterial hypertension in varying degrees of severity, two being in the malignant stage and two in severe and two in moderately severe stages. Patients were placed on the diet for three to five weeks.

In four patients the average diastolic blood pressure changed less than 10 mm. Hg. In the other two it fell 11 and 13 mm. Hg while on the diet but did not return to the control level when a normal diet was substituted.

An attempt was made to determine whether the limitation of salt intake imposed by the special diet played a part in the observed effects upon blood pressure. Serum chloride levels fell in all cases, but the serum sodium concentration did not. Addition of sodium chloride to the diet produced no consistent effects upon blood pressure. Weight was lost by four patients.

It is concluded that the effects of the rice and fruit juice diet upon blood pressure were minimal and inconsequential. Effects which were observed could not be correlated with changes in the salt content of the diet.

54. FURTHER STUDIES WITH THE HISTAMINE TEST FOR PHEOCHROMOCYTOMA

GRACE M. ROTH, PH.D., AND WALTER F. KYALE, M.D., ROCHESTER, MINN.

Previously we reported on the intravenous injection of small amounts of histamine base as a test for distinguishing the syndrome of pheochromocytoma from other clinical conditions. At that time, the injection of 0.05 or 0.025 mg. of histamine base produced the clinical syndrome, including hypertension and the characteristic symptoms, in three patients known to have pheochromocytoma. After surgical removal of the tumor, the injection of the same amount of histamine produced no paroxysm of hypertension or symptoms. As a result, we tentatively suggested this method as a test for the clinical syndrome of pheochromocytoma.

We now wish to present two additional cases of pheochromocytoma. In one of these, paroxysmal hypertension was present and the result of the histamine test was positive. The test was of proved value in arrival at the diagnosis. In the second patient, persistent hypertension with edema of the optic discs was present. The result of the histamine test in this case was regarded as negative because the increase in blood pressure after the injection of histamine did not exceed the increase in blood pressure during the cold pressor test. The failure to secure a positive result in this case of persistent hypertension may possibly be explained on the basis that the tumor contained only a relatively small amount of epinephrine (62 mg.) and that it was probably incapable of secreting sudden explosive charges of epinephrine because it was secreting epinephrine continuously.

A total of four cases, however, can now be reported in which the injection of histamine into patients with pheochromocytoma will produce an "attack" exactly similar to that of which they complain, in which marked elevation of the blood pressure occurs.

Tetraethylammonium chloride failed to produce a paroxysm of hypertension on two occasions in the patient known to have a pheochromocytoma.

The histamine test has been carried out on 200 patients with hypertension and fifty other patients with other clinical conditions. No untoward effects have been experienced by any of these patients. This would seem to indicate that the test is not hazardous.

55. DIRECT MEASUREMENT OF BLOOD PRESSURE IN THE RADIAL AND FEMORAL ARTERIES DURING AND AFTER TILTING

ROBERT S. GREEN, M.D. (BY INVITATION), ARNOLD IGLAUER, M.D., AND
JOHNSON MCGUIRE, M.D., CINCINNATI, OHIO

Direct tracings of radial and femoral artery pressure were obtained by a Satham Strain Gauge during and after tilting at a moderate rate between the 20 degree erect and 45 degree head-down position. The recordings from the radial artery were made with the arm maintained in a horizontal plane throughout the tilt.

Blood pressure in the radial artery invariably rose during the tilt from the head-up to the head-down position. In normal subjects, this increase of blood pressure (average, 19 mm. systolic/14 mm. diastolic) was followed by a fall, the blood pressure returning within eight to eighteen seconds to approximately the level of the head-up position. During the return tilt to the head-up position, the blood pressure always fell. In normal subjects, the pressure decreased (average, 14 mm. systolic/13 mm. diastolic) to a level less than in the initial erect position and returned within eight to eighteen seconds to approximately the initial level in the erect position.

The blood pressure in the femoral artery fell during the tilt from the head-up to the head-down position, and in the normal subjects then fell further, reaching a stabilized level in eight to eighteen seconds. During the return to the head-up position, the femoral blood pressure always increased, and in normal subjects this increase was followed by a further rise, the blood pressure reaching the range of the starting level in eight to eighteen seconds.

The increase in radial artery pressure and the decrease in femoral artery pressure during the tilt from the erect to the head-down position and the opposite changes during the return tilt indicated that these alterations are secondary to gravity. Since these primary changes were followed in both arteries by a fall of blood pressure in the head-down position and by an elevation of blood pressure in the erect position, it is believed that these secondary responses were neurogenic. The changes in the radial artery are interpreted as a reflection of the changes in the large arteries arising from the aortic arch, since the arm was maintained at the level of the arch throughout the tilt. The neurogenic responses tended to maintain the blood pressure at a stable level at the region of the aortic arch. This suggests that the purpose of these reflex adjustments of blood pressure is to protect the brain and perhaps the heart from adverse pressure changes.

56. CLINICAL AND EXPERIMENTAL STUDIES ON THE EFFECTS OF DIATHERMY ON BLOOD FLOW

KHALIL G. WAKIM, M.D., PH.D., J. F. HERRICK, PH.D. (BY INVITATION), AND
JEROME GERSTEN, M.D. (BY INVITATION), ROCHESTER, MINN.

In normal individuals as well as in patients (none of whom had any impairment in circulation), the blood flow in the upper and lower extremities was studied by the use of the plethysmograph with a compensating spirometer recorder before and for thirty to thirty-five minutes after application of diathermy for half an hour. Within five to fifteen minutes after diathermy, in seven of the twenty-five patients, the blood flow in the treated extremity increased more than 100 per cent. The increase in blood flow in the twenty-five patients ranged from 39 to 268 per cent, with an average increase of 71 per cent. At the same time the untreated extremities showed an average increase of 5 per

cent, but in nine of the twenty-five patients the untreated extremity showed an initial decrease in blood flow. At the end of thirty minutes after stopping the diathermy treatment, the blood flow in the treated extremities still showed an average increase of 56 per cent over the control value. There was no significant difference between the results obtained on patients and on normal individuals.

In dogs anesthetized with pentobarbital sodium, the blood flow was studied, by means of a bubble flowmeter in the femoral artery or vein, before, during, and after application of diathermy to the thigh for a period of twenty minutes. During the application of diathermy the significant increases over the control blood flow ranged from 16 to 209 per cent, with an average increase of 69 per cent. In four of the seventeen experiments slight decreases of 24 per cent, 18 per cent, 5 per cent, and 5 per cent, respectively, from the control blood flow occurred. After treatment with diathermy was stopped, the significant increases in blood flow ranged from 16 to 142 per cent, with an average increase of 64 per cent. In two of the seventeen experiments there was a slight decrease in blood flow after treatment with diathermy was stopped; namely, 15 and 10 per cent, respectively. In one experiment blood flow did not change after cessation of diathermy. Subcutaneous and muscle temperatures were taken in the dog by means of needle thermocouples and were recorded galvanometrically. The increase in muscle temperature at the end of the application of diathermy ranged from 0.9 to 9° C., with an average increase of 4.0° C.

57. A QUANTITATIVE HYPOTHERMAL METHOD FOR PRODUCTION OF LOCAL INJURY TO TISSUE

(GEORGE M. HASS, M.D., AND C. B. TAYLOR, M.D. (BY INVITATION) CHICAGO, ILL.

Local necrosis of tissue can be produced rapidly and quantitatively by use of an instrument cooled to a low temperature by internal expansion of carbon dioxide or flow of cold liquids. The cooling element of the instrument is flat and circular, so that when it is applied to the surface of an organ or tissue, cylindrical lesions are produced. The diameters of the lesions can be varied from 2 to 25 mm. by using cooling elements of comparable diameters. The depths of lesions can be varied from 1 to 13 mm. by varying the time of contact of the cooling element with the tissue. Volumes of injured tissue can be accurately determined by measurement. Lesions of identical size and location may be reproduced in successive experiments. Lesions have been produced in cartilage, bone, skin, skeletal muscle, vascular walls, heart, liver, kidneys, and brain of rabbits. Necrosis is uniform throughout the lesions and there is a sharp line of demarcation between nonviable and normal tissue at the periphery. Suppuration does not occur and hemorrhage is never found except around blood vessels in lesions of the brain. Organs and tissues can be progressively and selectively destroyed in a manner which is not possible by other methods such as cauterization, vascular ligation, or surgical excision.

38. ANEURYSMS OF THE CORONARY ARTERIES DUE TO POLY-ARTERITIS NODOSA OCCURRING IN AN INFANT: REPORT OF A CASE WITH CORONARY ARTERY THROMBOSIS AND MYOCARDIAL INFARCTION

C. M. PICKARD, M.D., J. G. OWEN, M.D., G. J. DAMMIN, M.D., St. Louis, Mo.

(INTRODUCED BY W. B. WOOD, JR., M.D.)

Since polyarteritis nodosa occurs infrequently in infancy and aneurysms of the coronary arteries with coronary artery thrombosis and myocardial infarction represent a rare complication, the following instance involving a 15-month-old infant is reported.

The patient, a white female infant, had been well until the age of 1 year, at which time because of rash and fever of three days' duration the patient was admitted to the Children's Hospital, St. Louis. The infant appeared acutely but not critically ill. The temperature was 39° C. In addition to the rash which was believed to represent an erythema multiforme, there was marked conjunctivitis and pharyngitis. The tympanic membranes were edematous. The remainder of the physical examination revealed nothing pertinent. The blood showed a leucocyte count of 16,000 with normal differential and a hemoglobin of 9 Gm. per cent. Tuberculin and Kline tests were negative and no pathogens were identified in urine, stool, and throat cultures. The rash began to fade on the fourth hospital day but the infant continued to appear ill. The temperature remained between 38 and 40° C. until the tenth day and then slowly subsided. The patient was discharged as improved on the seventeenth hospital day.

Three months later, on Sept. 16, 1946, the patient was readmitted because of dyspnea, orthopnea, anorexia, and fatigue on slight exertion of three weeks' duration. She appeared acutely and chronically ill. The heart and respiratory rates were rapid and the heart sounds of poor quality. Cardiac enlargement and pulmonary congestion were demonstrated by fluoroscopy. Blood examination revealed a leucocyte count of 10,400 per cubic millimeter, a moderate lymphocytosis, and hemoglobin of 10 Gm. per cent. Several hours after admission the infant suddenly became rigid, made some convulsive movements, and ceased to breathe. Emergency therapy revived the patient only temporarily and she expired five hours after admission.

At autopsy the heart presented the most significant and interesting findings. It weighed 80 grams (normal, 50 grams). The left coronary artery had a normal ostium but the lumen was narrowed to pin-point size at the bifurcation. The anterior descending branch of the left coronary artery presented a fusiform enlargement which began 3 mm. from its origin and extended for a distance of 15 millimeters. It measured 10 mm. in its greatest diameter. An adherent thrombus measuring 30 mm. and completely occluding the lumen was found in this branch of the left coronary artery. A portion of the thrombus occluded the circumflex branch at its origin. For most of its course the circumflex branch had a thickened wall and narrowed lumen. Fifteen millimeters from its origin the right coronary artery presented an aneurysmal dilatation measuring 18 mm. in length and 6 mm. in diameter. The wall of the artery was thickened for the initial 35 mm. of its course.

The left ventricle was dilated and the wall thickened (8 mm.) at the base but thin (3 mm.) at the apex. There were evidences of recent and remote infarction in the anterior portion of the interventricular septum and the anterior and apical portions of the left ventricle. The right ventricular wall was hypertrophied (6 mm.). Microscopically vascular changes representing healing and

healed polyarteritis nodosa were observed. Diffuse fibrosis and numerous areas of fresh infarction were found in sections of the anterior and apical portions of the myocardium of the left ventricle and the anterior portion of the septum.

59. ORAL MERCURIAL DIURETICS IN AMBULATORY PATIENTS WITH CONGESTIVE HEART FAILURE

SANFORD R. COURTER, M.D., AND JOHN S. PEARSON, M.D., CINCINNATI, OHIO

(INTRODUCED BY JOHNSON MCGUIRE, M.D.)

Previous reports of the use of oral mercurial diuretics in the treatment of the decompensated cardiac patient have stressed their use during hospitalization. We are presenting a preliminary report of the use of orally administered mercurial diuretics upon ambulatory patients seen in the Cardiac Clinic of the Out-Patient Dispensary at the Cincinnati General Hospital.

Fifty-six patients with cardiac edema have been treated from three to six months with orally administered mercurial diuretics, using Mercuzanthin.* All patients had previously received mercurials parenterally. The type of heart disease in twenty-six was hypertension; in fourteen, rheumatic; in eight, arteriosclerotic; in seven syphilitic; and in one, congenital.

The dosage schedule has varied, but a majority of patients now under treatment are taking two or three tablets daily. A minority take three tablets two or three times weekly.

To determine the adequacy of renal function, measurement of the blood urea nitrogen and a complete urinalysis were performed on each patient prior to initiation of therapy. Repeat blood urea nitrogen determinations were performed monthly, and urinalysis was done bimonthly.

Clinical improvement was gauged objectively by weight loss, decrease of edema and râles, increase in vital capacity, decrease in venous pressure; and subjectively by decrease in effort dyspnea, orthopnea, and paroxysmal nocturnal dyspnea.

Of the fifty-six patients treated, forty are currently receiving therapy. Thirty-five are considered improved and five unimproved. In nine patients the treatment has been discontinued for various reasons; these include four instances of painful stomatitis and two of diarrhea. Seven patients have died during the course of therapy; however, a review of the clinical records and autopsy protocols does not suggest that death was the result of mercurial toxicity. No renal complications have been observed. Stomatitis has appeared in eight patients, sufficiently severe to require discontinuance of therapy in four. Abdominal symptoms consisting of nausea, vomiting, abdominal cramps, and diarrhea have appeared in eight patients; treatment was stopped in three. Therapy was later restarted and continued successfully in one of these.

Our conclusion is that oral mercurial diuretics frequently can effectively replace parenteral mercurials in the ambulatory patient and that such replacement has materially reduced the daily patient load in this Cardiac Clinic.

*Mercuzanthin (Distributed by Campbell Products, Inc., New York, N. Y. Each tablet is equivalent to 0.030 Gm. mercury and 0.027 Gm. anhydrous theophylline).

60. PHYSIOLOGIC ADJUSTMENTS TO SUDDEN CHANGES IN ENVIRONMENTAL TEMPERATURE AND HUMIDITY OF HEALTHY YOUNG SUBJECTS AND CARDIAC PATIENTS

NATHANIEL GLICKMAN, M.S. (BY INVITATION), ROBERT W. KEETON, M.D.,
TOMRU INOUYE, A.B. (BY INVITATION), FORD K. HICK, M.D., STANLEY
E. TELSER, M.D. (BY INVITATION), IRWIN R. CALLEN, M.D.
(BY INVITATION), AND CHARLES A. GIANASI, M.D.
(BY INVITATION), CHICAGO, ILL.

Physiologic adjustments of healthy young male medical students to sudden changes in environmental temperature and humidity have been studied. The subjects remained for one hour in a comfortable environment (76° F. with relative humidities of 30, 60, or 80 per cent) and then entered a hot moist environment of (98.5° and 66 per cent relative humidity) for one or two hours. Then they re-entered the comfortable room and remained for one hour.

When subjects entered a hot moist environment from a comfortable environment, their mean skin temperature rose quickly and approximated its maximum value in less than ten minutes. The rectal temperature decreased with the first ten minutes and then slowly increased. The pulse rate and systolic pressure increased slightly while the diastolic pressure decreased slightly.

When they entered an environment conditioned for comfort from a hot moist environment, the mean skin temperature fell rapidly but it fell less rapidly when the relative humidity was high (80 per cent). The rectal temperature increased within the first ten minutes and then slowly decreased. The blood pressure showed no significant variation, although large fluctuations were occasionally observed. The pulse rate decreased but it decreased less when the relative humidity was high (80 per cent). In addition, the subjective sensation of comfort was obtained earlier and the evaporative weight loss per gram of moisture present on the skin and in the union suit was less when the relative humidity was high.

Patients with cardiovascular impairment (arteriosclerotic heart disease, angina pectoris following coronary infarction, hypertensive heart disease, rheumatic heart) are now being studied under comparable experimental conditions. In addition to the observations mentioned, determination of plasma volume, vital capacity, basal metabolic rate, and the effects of Master's two-step tests were made to define the degree of circulation impairment. Preliminary data on these impaired older patients reveal that their thermal adjustments are accomplished with equal ease and no clinically significant greater strain on the cardiovascular system occurs than that shown by the healthy young medical students.

61. A CARDIAC FACTOR WHICH INCREASES CORONARY FLOW UNDER SYMPATHETIC STIMULATION

R. W. ECKSTEIN* (BY INVITATION), M. W. STROUD (BY INVITATION),
W. H. PRITCHARD AND C. V. DOWLING† (BY INVITATION), CLEVELAND, OHIO

Stimulation of the stellate ganglion and cardiac nerves was shown by Gregg and Shipley to increase coronary blood flow. The exact mechanism of this change remains unknown.

In a further study of this problem in the anesthetized open-chest dog, blood flow in the left anterior descending or left circumflex coronary arteries was

*Rees Fellow in Medicine.

†Life Insurance Medical Research Fellow.

measured by a recording rotameter and a phasic flow meter either under the normal pulsatile aortic pressure or under a constant perfusion pressure. Flow measurements were made before, during, and after stimulation of the left cardiac accelerator nerves both before and after section from the stellate ganglion.

When both mean and phasic flows were recorded simultaneously, mean flow often increased before the phasic flow meter revealed any change in the resistance to flow as indicated by a constant rate of diastolic flow. Inspection of aortic and intraventricular pressure curves showed a marked shortening of cardiac contraction, as described by Wiggers and Katz, following cardiac nerve stimulation and during the action of adrenalin. In addition to the systolic shortening, our records show a marked increase in the rate of diastolic relaxation.

Actual flow measurements and calculations of increases in absolute lengths of diastole during minute intervals (from intraventricular curves) show that these alterations in systolic and diastolic time ratios account for from 10 to 30 per cent increases in flow, in addition to further increases due to decreased resistance to flow. In this manner, the heart, by its increased velocity of contraction and relaxation, reduces the time of intramyocardial vascular compression during systole, thus substituting longer periods of the high diastolic flow for long periods of low systolic flow despite moderate increases in heart rate. Since the highest rate of coronary blood flow occurs in diastole, it follows that any lengthening of the total diastolic time in a given minute must increase mean blood flow.

These studies are being continued in an effort to evaluate other mechanical factors responsible for increasing coronary flow after nerve stimulation such as changing heart size, intramyocardial tension, and increased vascular emptying resulting from the augmented vigor of contraction.

62. THE VENTRICULAR GRADIENT IN HYPERTHYROID CONDITIONS

ROBERT B. FAILEY, JR., M.D., AND ALBERT L. HYMAN, M.D., CINCINNATI, OHIO
(INTRODUCED BY JOHNSON MCGUIRE, M.D.)

In a study of the effect of hyperthyroidism and of thyroid substance on the heart, the electrocardiograms of a group of cases were analyzed by study of their ventricular gradients. These cases were of two groups, the first composed of fourteen patients with hyperthyroidism and the second of eleven normal subjects to whom 6 grains of thyroid substance were administered daily. All patients studied were free of complicating diseases and all had electrocardiograms that were normal except for a few instances where transient abnormalities of cardiac rhythm were noted.

In the group with hyperthyroidism all of the fourteen patients showed an increase in the magnitude of their ventricular gradient as compared with control electrocardiograms taken after remission of the disease induced by surgery or by thiouracil. This increase averaged 39 per cent, with a range from 4 to 100 per cent. In addition, seven of this group showed a significant clockwise shift in the direction of the ventricular gradient averaging 26 degrees, with a range of plus 16 to plus 48 degrees. The other seven in this group showed no significant shift in the direction of the gradient.

In the group receiving thyroid extract, all of the eleven subjects showed an increase in magnitude of the ventricular gradient. This magnitude averaged 30 per cent, with a range from 7 to 73 per cent. None of these subjects showed any significant shift in direction of the gradient.

In both groups increase in heart rate was a common occurrence, and values obtained for magnitude and direction of ventricular gradients were corrected for changes in heart rate.

It is suggested that the increased magnitude of the ventricular gradient is a reflection of the increased work of the heart. It is also suggested that the shift in direction of the gradient in the hyperthyroid group may indicate myocardial strain since this finding has been previously noted in cases of hypertension and of acute glomerular nephritis.

63. THE PRECORDIAL ELECTROCARDIOGRAM IN LEFT VENTRICULAR HYPERTROPHY: A STUDY OF AUTOPSIED CASES

PAUL H. NOTH, M.D., GORDON B. MYERS, M.D., AND HOWARD A. KLEIN, M.D.

(BY INVITATION), DETROIT, MICH.

An analysis has been made of the Wilson precordial leads in eighty-four pathologically proved cases of left ventricular hypertrophy without associated myocardial infarction or appreciable gross fibrosis. This comprises all cases occurring within a five-year period in which satisfactory electrocardiograms were obtained within three months of death except for thirty-seven cases of bundle branch block.

By means of a Cambridge device, measurements of the time elapsing from the onset of QRS to the nadir of Q, to peak of R, to nadir of S, and to end of QRS were made in three complexes of Leads $V_1, 6$. The average amplitude of the individual components of the QRS, the contour and level of the RST segment, and the amplitude and direction of the T waves were determined in each precordial lead. Similar measurements were made in a control series of fifty-two cases in which the hearts were normal at autopsy, and in a second group of fifty young male adults with normal hearts by physical and roentgen examination.

Differentiation between pattern of left ventricular hypertrophy and of normals could not be made from the amplitude of the R waves in V_5 and V_6 alone since the average values were only slightly higher in the former.

In 98.0 per cent of normals the time interval from the onset of QRS to peak of R was less than .05 second. In 93.1 per cent of normals the time interval from onset of the R wave to its peak was less than .04 second. For purposes of classification, measurements equalling or exceeding these figures were regarded as abnormal. A Q-R of .048-.049 and/or an R of .038-.039 second were regarded as borderline and values below this, as normal. Of the eighty-four patients with left ventricular hypertrophy, thirty-four (or 40.5 per cent) showed an abnormal Q-R and/or R duration. The average cardiac weight in this group was 610 grams. Eight (or 9.5 per cent) showed borderline values and the cardiac weight averaged 569 grams. Forty-two cases (or 50 per cent) showed normal values, with an average cardiac weight of 536 grams. There was a general trend toward increasing duration of Q-R or R with increasing cardiac weight, but many individual exceptions were encountered.

In eight cases where R or RST-T findings in precordial Leads V_5 and V_6 were borderline or normal, abnormalities referable to left ventricular hypertrophy were found either in V_7 , or in the unipolar extremity leads.

In seven cases the electrocardiogram showed nonspecific abnormalities and in four it was regarded as normal.

64. THE FORM OF THE ELECTROCARDIOGRAM IN ANTEROSEPTAL MYOCARDIAL INFARCTION COMPLICATED BY RIGHT AND LEFT BUNDLE BRANCH BLOCK

FRANCIS F. ROSENBAUM, M.D., AND HERBERT W. POHLE, M.D. (BY INVITATION)
MILWAUKEE, WIS.

Clinical and experimental studies have shown that although the electrocardiographic diagnosis of anterior infarction can be made in the presence of right bundle branch block, the characteristic signs of myocardial infarction are obscured by left bundle branch block unless the infarct involves the interventricular septum. Observations have been made in two patients in whom anteroseptal myocardial infarction was complicated first by transient right bundle branch block and then by transient left bundle branch block. This permitted an unusual opportunity to compare in the same individuals the standard and precordial electrocardiograms in normal conduction and both types of intraventricular block in the presence of myocardial infarction.

The first patient was a man aged 50 years, who had a typical acute coronary thrombosis without antecedent cardiac symptoms. When right bundle branch block was present the standard electrocardiograms showed large S waves in all leads, while records from the right precordium displayed prominent Q waves and large late R deflections. When left branch block was present, Lead I showed no negative deflections and the large Q waves and late R peaks previously recorded from the right, now appeared over the left precordium. The characteristic signs of infarction were confined to Leads CR₂ and CR₃ when normal conduction was present. Partial heart block and complete localization of the infarct and the extension into the septum were confirmed at post-mortem examination.

The second patient was a man aged 52 years who had possible mild angina pectoris for several months before the acute infarction occurred. Large, late R waves were again recorded from the right precordium when the right branch of the His bundle was blocked and large Q or QS waves appeared in all of the precordial leads. When left branch block developed, tracings taken from the left precordium resembled those recorded over the right precordium during the period of right branch block; prominent waves appeared in Lead I. The precordial electrocardiogram during normal conduction suggested that the infarct was anteroseptal in location. The clinical course was complicated by paroxysmal auricular fibrillation but a satisfactory recovery occurred.

In anterior myocardial infarction complicated by intraventricular block, the ventricular complexes recorded from the precordial area overlying the ventricle which is activated late are very similar in form in both right and left bundle branch block in those cases in which the myocardial lesion also involves the interventricular septum.

65. ELECTROCARDIOGRAPHIC CHANGES AFTER ELECTRIC SHOCK TREATMENTS

VERNON L. EVANS, M.D., AURORA, ILL.

In persons with suspected heart disease, but normal electrocardiograms, it has been possible to produce abnormalities in the electrocardiograms by partial oxygen deprivation (Levy) or by measured exercise (Masters). The cases presented here were patients with definite electrocardiographic abnormalities who were subjected to the extreme anoxemia and violent exercise

produced by psychiatric electric shock treatments. To the surprise of the writer, the electrocardiograms assumed a more normal pattern for a few minutes after the treatment.

Case 1 was a man 47 years of age who had suffered a coronary occlusion four years previously. Before treatment the electrocardiogram showed low to flat T waves in Lead I and slightly inverted T waves in Lead II. Immediately after treatment, the inverted T waves became flat.

Case 2 was a 59-year-old woman who had hypertension and a partial hemiplegia. An electrocardiogram showed sharply inverted T waves in Leads I and CF IV and V. Immediately after electric shock treatment the previously inverted T waves had become flat to upright. One minute after treatment they were slightly inverted, two minutes after treatment they were more inverted, and three minutes after treatment they were just about the same as before treatment.

Case 3 was a 41-year-old man who had had a coronary occlusion two months before electric shock treatment. The electrocardiogram showed sharply inverted T waves and deep Q waves in Leads II and III. Immediately after treatment there was a partial cardiac arrest, the rate falling to 20 per minute. The T waves remained inverted. However, the QRS complexes became upright to diphasic.

Case 4 was a 73-year-old woman whose physical examination was negative and who gave no history of cardiac disease. Her electrocardiogram before treatment showed inversion of the T waves in Lead CF IV. Immediately after treatment the T waves became upright. They remained upright for three minutes, then became flat and remained flat for another ten minutes, and at the end of twenty minutes they had become inverted and had resumed their pre-treatment configuration.

Case 5 was a 40-year-old woman with no history of cardiac disease. The T waves were found to be low to flat in Lead I and flat in Lead CF IV. Immediately after treatment the T waves in Lead I had become upright. They remained upright for three minutes and then resumed their previous flat condition.

The small number of cases presented do not warrant any conclusions. It may be said that the increase in amplitude or return to normal of the T waves are the physiologic response to exercise, such as one sees in normal athletic hearts. However, this is not the response in the Masters test, and the foregoing may be considered an extreme exaggeration of this test.

As compared with the tests of Masters and Levy, these results seem paradoxical.

66. THE EFFECT OF A SINGLE INSPIRATION IN LEAD III AND LEAD CF IV OF THE HUMAN ELECTROCARDIOGRAM

GEORGE L. NORRIS, M.D. (BY INVITATION), AND EDWARD MASSIE, M.D.
ST. LOUIS, MO.

The effect on the electrocardiogram of a single deep inspiration during Leads III and CF IV was studied in order to (1) ascertain the frequency and type of respiratory changes produced; (2) determine if any correlation exists between these changes and the presence or absence of heart disease; and (3) determine the influence of digitalis on these respiratory variations. Two thousand three hundred seven consecutive tracings were obtained for this study.

An initial increase in rate followed by slowing of various degrees frequently occurred, but in very few instances was it possible to demonstrate changes in the auriculoventricular conduction with the changes in rate. Digitalis was associated with the most striking changes in rhythm including usually a shift of the pacemaker from the sinoauricular node toward the auriculoventricular node, but the depression of the pacemaker also occurred in the absence of digitalis.

Numerous changes including variations in contour of P waves, QRS complexes, and T waves in Lead III were almost as frequent in normal as in abnormal records. The QRS complexes usually returned to their original configuration very shortly after the T waves assumed their previous form.

In Lead III of normal records there was a decided tendency for inspiration to result in increasing positivity of all deflections, but in Lead CF IV there was a tendency for inspiration to cause increasing negativity of all deflections. In abnormal electrocardiograms, except in those of patients with acute myocardial infarction or in those of subjects under digitalis therapy, inspiration tended to increase the positivity of all deflections in Lead III. In the patients who received digitalis, or who had acute myocardial infarction, inspiration tended to increase the negativity of the T waves in Lead III with an opposite effect on the other deflections. The frequency of T-wave changes in Lead CF IV with inspiration detracts from the significance of the T wave in the fourth lead in the interpretation of borderline records.

Respiratory effects on the electrocardiogram include changes in axis, in T waves, and in cardiac mechanism. It has been suggested that the axis changes are probably the result of extracardiac factors, that T-wave changes are probably the result of intracardiac factors, and that variations in cardiac mechanism are the result of nervous reflexes, chiefly vagal.

67. AN UNUSUAL VAGOVAGAL REFLEX TYPE OF ADAMS-STOKES SYNDROME

HOWARD L. CORRELL, M.D., AND M. C. F. LINDERT, M.D., MILWAUKEE, WIS.

(INTRODUCED BY MAURICE HARDGROVE, M.D.)

A patient with a vagovagal type of reflex Adams-Stokes syndrome associated with an anterior traction diverticulum of the esophagus was studied. Spontaneous attacks occurred when cardiospasm caused irritation of the diverticulum through dilatation of the esophagus, and the vagal reflex sensitivity was increased by digitalization. Minor clinical attacks and electrocardiographic evidence of cardiac slowing or arrest occurred in the digitalized patient on distention of a balloon inserted in the esophagus to the level of the diverticulum, but not above or below that level. Right carotid sinus stimulation caused the same phenomenon. Atropine abolished these findings through interruption of the vagal reflex. Withdrawal of digitalis resulted in decreased sensitivity of the carotid sinus and vagovagal reflex irritability to a point where the clinical and electrocardiographic findings were not obtained. Intravenous administration of 0.8 mg. of digitoxin caused re-establishment of the carotid sinus and vagovagal reflex irritability within four hours.

This is the second case, known to us, of Adams-Stokes syndrome due to vagovagal reflex associated with an esophageal diverticulum and the first in which the summation role of digitalis in producing the syndrome has been reported. This summation role of digitalis in reflex types of cardioinhibitory Adams-Stokes syndrome seems worthy of note.

68. THE VARIABILITY OF THE FASTING NOCTURNAL GASTRIC SECRETION IN NORMAL INDIVIDUALS AND IN PATIENTS WITH DUODENAL ULCER

ERWIN LEVIN, M.D. (BY INVITATION), JOSEPH B. KIRSNER, M.D., PH.D.
WALTER L. PALMER, M.D., PH.D., AND CARRIE BUTLER, B.S.
(BY INVITATION), CHICAGO, ILL.

The fasting nocturnal gastric secretion was measured in thirty-three normal individuals and in thirty-two patients with active duodenal ulcer. The average twelve-hour volume, concentration of hydrochloric acid, and total output of acid were significantly higher in patients with duodenal ulcer than in normal individuals. In the normal group, the volume averaged 581 ml.; the free acidity, 29 clinical units; and the total output of acid, 661 milligrams. In the duodenal ulcer series, the volume averaged 1,004 ml.; the free acidity, 61 clinical units; and the total output of acid, 2,242 milligrams. Similarly, the average hourly secretion was persistently higher in patients with duodenal ulcer than in normal individuals. Wide individual variations were observed in both groups.

In addition, considerable spontaneous fluctuation in the hourly and total night secretion was noted in the same individual. Thus, in the normal subjects, the average percentage variations in the volume, free acidity, and total output in the same individual were 24, 44, and 47 per cent, respectively. In patients with duodenal ulcer the average spontaneous variation was: volume, 17 per cent; free acidity, 24 per cent; and total hydrochloric acid output, 23 per cent. The volumes in both groups were significantly higher during the first six hours of the night as compared with the last six hours. There was no important difference in the average concentration of free hydrochloric acid during the various periods of the night in the normal subjects, whereas in the duodenal ulcer series, the output of acid was significantly lower during the last three hours of the night than at any other time.

These variations occurring spontaneously in the same individuals must be taken into account in the proper evaluation of procedures utilized for the purpose of reducing gastric secretion.

69. ATROPHIC GASTRITIS AND MALNUTRITION

LEONIDAS H. BERRY, M.D., CHICAGO, ILL.

Most of the conceptions and investigations into the causes of gastritis in the past have been concerned with extrinsic factors and local irritation. It is probably true that next to the skin the organ which is subjected to the most rigid abuse from man's external environment is the stomach. Today investigators show a definite trend of interest in the role of intrinsic factors in gastric disease. Psychosomatic factors are being emphasized.

Our studies of patients with chronic atrophic gastritis show the etiologic importance of malnutrition and indicate that most of the chronic atrophic gastritis coming under our observation is probably primary rather than inflammatory. Malnutrition not due to disease, most commonly but not invariably, follows an economic pattern. This fact was very striking in our studies.

The analysis of data on 706 dyspeptic patients gastroscooped 1,000 times during four years immediately preceding World War II showed some striking differences when compared with 297 patients with dyspepsia gastroscooped 364 times during the four war years. In the "prewar" group (1937 to 1942) 53.6

per cent of the total chronic gastritis seen was the atrophic type. The remaining 46 per cent was about equally distributed between the chronic superficial and chronic hypertrophic types. The "wartime" group (1942 to 1946) showed a considerable decline in chronic atrophic gastritis (from 53.6 per cent to 18.5 per cent) and a corresponding rise in the superficial and hypertrophic types. Thus chronic "atrophic gastritis" was three times higher in the "prewar" group. What is the significance of this variation in distribution? Rather extensive laboratory studies were done. A large percentage of the "prewar" group had dietary questionnaire and food habit studies. Ninety per cent of the "prewar" group were clinic patients, unemployed from two to four and up to eight years prior to examination. Nutrition diaries clearly showed that most of these patients existed on diets inadequate in quantity and quality of protective foods to maintain normal nutrition. There were evidences of low or borderline plasma ascorbic acid levels, red blood cell counts, hemoglobin values, spongy gums, underweight, and other evidences of subclinical states of under-nutrition. Symptomatically those patients with so-called atrophic gastritis were fatigued easily and had attacks of weakness in addition to abdominal distress.

As employment improved the ratio of patients on relief to those gainfully employed was reversed. Therapeutic studies (reported in another communication) making use of liver extract, vitamin B complex, and improved diets showed striking symptomatic improvement and convincing disappearance of atrophy. These facts contribute further evidence to the etiologic relationship of malnutrition to so-called chronic "atrophic gastritis."

70. THE EFFECT OF CHOLINE, METHIONINE, AND LOW FAT DIET ON THE LIFE EXPECTANCY OF PATIENTS WITH CIRRHOSIS OF THE LIVER

LEO WADE, M.D., St. Louis, Mo.

(INTRODUCED BY CARL HARRFORD, M.D.)

In a previous communication the following regimen for the treatment of cirrhosis was described:

1. Diet

Protein	90-100 grams
Fat (chiefly vegetable)	50 grams
Carbohydrate	Sufficient for patient's caloric needs
2. Drugs

Choline hydrochloride	1-8 grams
Methionine (1 quart skimmed milk)	0.9 grams
3. Vitamins

A	10,000 U. S. P. units
D	800 U. S. P. units
4. Abstinence from alcohol

This regimen was based on two assumptions: (1) that fatty changes in the liver ordinarily precede the more characteristic anatomic changes of cirrhosis; (2) that fatty changes in the liver are often dietary in origin, especially in the alcoholic patient, and are comparable to the changes observed in experimental animals placed on deficient diets. The present report summarizes the clinical experiences of the past six years, during which time some 224 patients with cirrhosis of the liver have been studied. The fate of these patients is compared with that of a similar group of 311 patients treated in the same hospital under similar circumstances prior to the use of the present therapeutic regimen.

The fate of the two groups of patients, as of March 1, 1947, is as follows:

	EXPERIMENTAL		CONTROL	
	NUMBER	PER CENT	NUMBER	PER CENT
Dead	168	77.1	265	85.2
Living	44	20.2	7	2.3
Fate unknown	12	2.7	39	12.5
Total	224	100.0	311	100.0

Comparison of the survivors in the two groups permits no conclusion regarding the merits of the therapeutic regimen since the period of observation of the experimental group has been too brief. The period of survival thus far from the onset of initial symptoms varies from 13.0 to 63.2 months for the experimental series as compared with 71.5 to 167.5 months for the control series. The average period of survival is 33.0 months and 112.2 months, respectively.

It is not possible to utilize all the patients known to be dead in the two series since some were thought to have died from causes not directly related to their liver disease. Adequate data regarding the onset of symptoms were not available in other instances. The experimental series is thus reduced to 138 patients and the control group to 196 cases.

If one plots the percentage of patients surviving at any given time after the onset of the initial symptoms, the curves for the experimental and control groups superimpose one upon the other. Similar curves comparing the survival rate after the onset of ascites, jaundice, or hemorrhage also reveal no difference between the experimental and control groups.

It is concluded, therefore, that the therapeutic regimen as carried out was without effect upon the life expectancy of patients with cirrhosis.

71. HEPATIC FUNCTION IN INFECTIOUS MONONUCLEOSIS

JOHN W. BROWN, M.D., JOHN LEROY SIMS, M.D., AND

JACK E. CLIFFORD, M.D., MADISON, WIS.

(INTRODUCED BY OVID O. MEYER, M.D.)

Liver function tests were performed one or more times in forty-eight consecutive cases during the course of infectious mononucleosis. The presence of infectious mononucleosis was established with reasonable certainty according to existing criteria.

The following tests were made one or more times on each patient with the results indicated: icterus index in 43 patients, abnormal values obtained in 16; urine urobilinogen in 33, elevated values in 20; cephalin cholesterol flocculation test in 47, value of 3 plus or more in 37; thymol turbidity in 41, value of 4 units or more in 16; prothrombin time in 41, levels below 75 per cent in 5; 2 mg. per kilogram twenty-minute bromsulfalein test in 21, 10 per cent or more retention in 1. Certain tests were performed three or more times in several patients. Of 24 patients who had the cephalin cholesterol flocculation test three or more times, 23 (96 per cent) attained a value of 3 plus or more at least once. Eleven of twenty patients who had thymol turbidity tests three or more times attained a level of 4 units or more at least once. For the patients who had a series of observations, the average period from onset of disease to last abnormal value for Hanger's test was 34.7 days, and for thymol turbidity test, 38.9 days. Persistence of symptoms was noted for a variable period after the liver function tests performed were normal in seven of fifteen patients with adequate follow-up. The tests to date have not revealed a significant correlation between the heterophile antibody reaction and Hanger or thymol turbidity test.

72. EXPERIENCES WITH NEEDLE BIOPSY OF THE LIVER IN PATIENTS WITH MALIGNANT HEPATIC NEOPLASM

LEON SCHIFF, M.D., CARL KUMPE, M.D., (BY INVITATION), STUART A. SANDI, M.D., (BY INVITATION), AND EDWARD A. GALL, M.D. (BY INVITATION)
CINCINNATI, OHIO

Needle biopsy of the liver was performed with the Vim-Silverman needle in forty-seven patients with proved malignant neoplasm of the liver. The transpleural approach was used in thirty-six of the patients and the abdominal approach in eleven. The tumor was primary in ten and secondary in thirty-seven. Neoplasm was demonstrated in the tissue obtained from thirty-nine of the group. The tumor was missed in eight biopsies, in three of which the specimen obtained was inadequate for microscopic examination.

The liver was palpated as nodular or irregular in twenty-nine of the patients and as smooth in seventeen. In one patient it was not palpable. The clinical diagnosis of malignant neoplasm of the liver was confirmed by means of the biopsy in thirty cases. In nine patients, three with primary hepatic tumor, carcinoma was not suspected prior to the biopsy. In sixteen of the twenty-nine patients with nodular liver, and in twelve of the twenty with smooth liver, the biopsy was the first means by which the presence of carcinoma was definitely established.

Liver biopsy proved particularly valuable in patients in whom the presence of carcinoma was not previously established and in whom "liver function" studies, especially the cephalin cholesterol flocculation test, suggested the presence of hepatitis.

Needle biopsy of the liver is a surprisingly valuable adjunct in the diagnosis of primary and secondary neoplasm of the liver and not infrequently may be the earliest or the sole means of establishing the diagnosis.

73. INFECTIOUS AND TOXIC HEPATITIS: PATHOLOGIC AND CLINICAL MANIFESTATIONS

HANS POPPER, M.D., FREDERICK STEIGMANN, M.D., MURRAY FRANKLIN, M.D. (BY INVITATION), AND LEO F. NARUT, M.D. (BY INVITATION), CHICAGO, ILL.

Studies in the Army Institute of Pathology on fatal cases of infectious (viral) hepatitis revealed a characteristic morphologic picture. Investigation of fatal cases of acute primary hepatitis observed in a civilian hospital during eighteen years showed in less than one-half a morphologic picture similar to the one seen predominantly in military personnel; these cases were considered to be infectious in origin. Since in many of the other cases a hepatotoxic etiologic factor was present, these were tentatively designated as toxic hepatitis. The main morphologic differences were slower cell death, slighter mesenchymal involvement, outspoken zonal distribution, and occasionally predominant fatty changes in the toxic cases. Applying similar differentiating points to biopsy specimens of thirty-seven cases of acute primary nonfatal hepatitis, usually a differentiation between infectious and toxic hepatitis was possible. Subsequently a correlation with the apparent etiologic factors was found. More than one-half of the studied cases revealed a morphologic picture designated as toxic.

Based on this differentiation, we attempted to divide the cases of acute primary hepatitis by clinical and laboratory methods. For instance, usually patients with toxic hepatitis are older and have a shorter prodromal period with

more intense gastrointestinal symptoms (vomiting and diarrhea) which continue even while the patient is in the hospital in contrast to infectious hepatitis in which the gastrointestinal symptoms decrease when jaundice appears. The patients with toxic hepatitis appears sicker, more feverish and dehydrated, are more often deeply icteric, and have tachycardia. Pruritis and dermatitis may be present. The spleen is more often felt. There is no clear-cut differentiation in the laboratory findings. In general, however, cephalin flocculation and thymol turbidity are more often negative and alkaline phosphatase and total cholesterol more often elevated in the toxic cases. In toxic hepatitis, the non-protein nitrogen is often elevated and in the fatal cases icteric nephrosis is common, some of the patients dying in uremia. The dehydration in toxic hepatitis may be held responsible for the renal involvement just as dehydration has been considered an important pathogenetic factor in lower nephron nephrosis.

Definite establishment of the etiologic factors in acute hepatitis by virus studies might justify the thus far tentative designation of infectious and toxic hepatitis. The present findings suggest two different entities and that not every case of acute primary hepatitis in civilians is of infectious origin.

74. METHIONINE IN THE TREATMENT OF CHRONIC AND ACUTE HEPATITIS

FREDERICK STEIGMANN, M.D., MELVIN SALK, M.D. (BY INVITATION), WILLIAM H. TODD, M.D. (BY INVITATION), AND HANS POPPER, M.D., CHICAGO, ILL.

Encouraged by results of treatment of experimental nutritional cirrhosis by lipotropic substances, methionine, choline, or choline plus cystine were used as supplement in patients with liver cirrhosis. While the reports on such regimes are few and on small series of cases, most of them are rather optimistic.

In a comparative study of different lipotropic substances during the past two years, a group of ten patients with hepatic cirrhosis received, in addition to a high protein, high carbohydrate, high vitamin, and low fat diet, daily 5 Gm. of methionine orally. Seven of the patients had ascites; all with the exception of three were jaundiced; their symptoms varied from ten days to five years. They were treated in the hospital from ten days to five months. Three patients died during the first stay in the hospital and seven recovered and were discharged. Of these, two returned six and twelve months later, respectively, and died during the second admission. Of the remaining five, two are still ailing, while three have returned to their previous occupation, at which they have remained so far nine to twelve months. The jaundice disappeared in the recovered cases; the ascites decreased in two, and in three paracentesis is still occasionally necessary. The liver function improved in the surviving cases, especially the albumin/globulin ratio and the cephalin flocculation. Some improvement of liver function occurred even in two patients who later died.

Comparison of the results of this group with another without lipotropic supplement reveals a definite improvement both as to mortality and recovery. It should be considered that the variations in the therapeutic effects are not only due to different clinical stages, but also possibly to different types of cirrhosis.

The evaluation of therapeutic results in acute hepatitis is difficult because of the erratic course of the disease. It appeared therefore more revealing to study the influence of methionine upon the nitrogen balance in patients with acute infectious hepatitis. In four such patients no protein-sparing effect was found in experiments composed of several five-day periods. These results

speaking against the existence of a methionine deficiency in acute infectious hepatitis due to diversion of methionine from protein formation to lipotropic or other liver-protecting activity.

75. PROGNOSTIC VALUE OF BIOPSY IN CIRRHOSIS OF THE LIVER

WILLIAM D. DAVIS, JR., M.D., NEW ORLEANS, LA.

(INTRODUCED BY THOMAS FINDLEY, M.D.)

Liver biopsies were accomplished in twenty-one patients with cirrhosis either by needle or surgical approach. Follow-up data were available in sixteen of these. In this paper an attempt has been made to determine the prognostic value of changes in the liver by correlating the degree of fatty change, fibrosis, necrosis, and inflammation in the liver sections with the response to therapy. The relation of ascites and the presence or absence of central veins was also noted. Treatment consisted of high carbohydrate (500 Gm.), high protein (200 Gm.), variable fat diet with supplements of brewer's yeast, vitamins, liver extract, and, in some instances, methionine or choline.

Of the group, eleven were considered to be decompensated and of these, regardless of the degree of fibrosis, necrosis, and inflammation, only those with rather severe fatty change showed significant improvement under treatment. In the compensated group microscopic changes were relatively minor and the clinical course was correspondingly good. In general, those patients with necrosis and inflammation showed better clinical and microscopic improvement than those with only fibrosis. The two patients with severe necrosis and inflammation without fatty change both died during the acute episode. Four other patients with similar changes plus considerable fatty infiltration have returned to useful life. In general, the patients with ascites showed relatively fewer central veins than those without ascites.

76. AN UNUSUAL CASE OF ESSENTIAL NORMAL CHOLESTEREMIC XANTHOMATOSIS

S. J. THANNHAUSER, M.D. (BY INVITATION), BOSTON, MASS., A. WIKLER, M.D. (BY INVITATION), AND THORNTON SCOTT, M.D., LEXINGTON, KY.

Extensive biochemical, roentgenographic, electroencephalographic, and histologic studies have been made in the case of a 38-year-old white man with cutaneous xanthomatosis and grand mal, nuchal, and psychomotor seizures.

The initial manifestations of the disease appeared two and one-half years before. There was no history of seizures prior to the development of xanthomatosis and no family history of seizures.

Electroencephalograms showed diffuse cerebral disorder with some left-sided localization, and marked abnormalities were elicited following left carotid pressure which produced temporary asystole and faintness.

Total cholesterol, 196 mg.; free, 48 mg., cholesterol esters, 148 mg. per 100 ml. of blood.

Roentgenograms of the skull were normal. The long bones showed medullary thickening in the lower portion of the shafts of the femora and humeri but no punched-out areas. Biopsy of the femur showed xanthomatous involvement.

The most unusual feature of the case was the finding of scattered petechiae and small raised mahogany lesions over the limbs and trunk which tended to

appear in crops and fade in a few weeks. In addition, he showed classical chamois-colored lesions involving the lids and the entire scalp. Biopsy of one of the petechiae showed infiltrations of reticuloendothelial cells and eosinophiles around small blood vessels. Such lesions are extremely rare in adults with xanthomatosis of this type.

The patient suffered a pathologic fracture near the biopsy site after release from the hospital. His seizures have been satisfactorily controlled with dilantin sodium.

This case appears to represent essential xanthomatosis of the normal cholesteremic type (eosinophilic granuloma, eosinophilic xanthomatous granuloma) involving skin, bone, and dura, with eosinophilic granulomas involving the small blood vessels of the skin.

77. "COMBINED ANTACID" THERAPY IN PEPTIC ULCER

ERWIN KAMMERLING, M.D. (BY INVITATION), AND FREDERICK STEIGMANN, M.D.
CHICAGO, ILL.

The large number of antacids available for the treatment of peptic ulcer indicates that no one substance is of value in all cases. The disadvantages of some of the currently used antacids are acid rebound, alkalosis, too-transient neutralization, interference with normal gastric function, and unpalatability. Hence, the search for better antacids continues. Recently we have studied the antacid effect of a substance which has been prepared with the idea of combining the properties of currently used antacids but eliminating some of the untoward effects. This substance is a mixture of aluminum hydroxide, magnesium trisilicate, and purified gastric mucin.

Twenty-five patients with symptomatology and x-ray evidence of ulcer (twenty duodenal and five gastric) were chosen for this study. The fasting stomach was aspirated at fifteen-minute intervals for one hour before 0.5 mg. of histamine phosphate was injected subcutaneously. Following this, five further aspirations were done. On successive days, two tablets of the new preparation, of Amphogel, or two Sippy tablets were chewed and swallowed following the fourth fasting aspiration and prior to the histamine injection. The free and total acidity was determined in all samples by titration with 0.1 N sodium hydroxide solution, using Töpfer's solution and phenolphthalein as indicators.

In 92 per cent of the cases, a variable antacid effect was obtained with all substances. In 55 per cent, the mucin mixture was more effective; in 27 per cent, less effective. In 18 per cent, they were equally effective. In 70 per cent of the cases, the mucin preparation was observed in the aspirated samples from fifteen to forty-five minutes longer than the other antacids. Recent gastroscopic and x-ray studies by Hardt confirmed this observation by demonstrating that the mucin preparation remained in the stomach longer. It was also noted that the mucin mixture was a more effective antacid when chewed than when allowed to dissolve in the mouth.

The preliminary antacid studies with this preparation which are now being supplemented by clinical observations suggest that this substance may prove a valuable addition to peptic ulcer therapy.

78. TRANSITION OF PANCREATIC EDEMA INTO PANCREATIC NECROSIS

H. L. POPPER, M.D. (BY INVITATION), AND H. NECHULES, M.D., Ph.D.
CHICAGO, ILL.

Pancreatic edema or pancreatic necrosis can be produced easily in the dog, but we have not been able, heretofore, to observe edema progress or change into necrosis. This has been achieved now by temporary clamping of the upper pancreatic artery in the presence of edema of the pancreas. It is felt that spasm of arteries may play a role in the development of pancreatitis.

79. BIOCHEMICAL FINDINGS IN ACETYL SALICYLATE THERAPY OF ACUTE RHEUMATIC FEVER

WILLIAM S. HOFFMAN, M.D., ITALO F. VOLINI, M.D., MARK POMARANC, M.D.
(BY INVITATION), AND CATHERINE NOBE, B.A. (BY INVITATION)
CHICAGO, ILL.

Eighty patients with acute rheumatic fever were treated with high doses of aspirin combined in tablet form with colloidal aluminum hydroxide (Alasil, Wander). Preliminary tolerance studies had shown that the plasma salicylate levels obtained after single doses of the aspirin product were of the same order as those obtained with ordinary aspirin. But the gastrointestinal disturbances obtained in 13 per cent of the patients on high doses of ordinary aspirin did not occur with the aspirin containing aluminum hydroxide.

From 94 to 144 grains of aspirin daily (about 120 mg. per kilogram) usually produced plasma salicylate levels around 30 mg. per 100 milliliter. At this level, symptoms of salicylism often occurred with an accompanying irresponsibility and negativism. Many patients refused further to cooperate with the treatment and these had to have the dosage lowered. Thus in only forty-one patients was an average level of more than 25 mg. per 100 ml. maintained. The patients were treated until subsidence of clinical symptoms.

There was no great difference in the percentage of patients whose sedimentation rate subsided to normal, whether average salicylate level was above or below 25 mg. per 100 milliliter.

The plasma prothrombin levels were not much altered. They were reduced below 75 per cent of normal in only 33 per cent of the cases. In only one patient was the level low enough to produce bleeding, which was relieved by one single injection of vitamin K. There was no greater incidence of reduced prothrombin concentrations in the patients with high plasma salicylate concentration than in those with lower levels.

In almost all patients, a moderate reduction in serum bicarbonate occurred, usually associated with increased chloride concentrations and with slightly lowered sodium concentrations. The serum pH was usually normal. This might have been due to primary alkalosis produced by hyperventilation, but there was no marked hyperpnea, the urine was never alkaline, and clinical improvement occurred with bicarbonate. These findings along with those obtained with salicylate and chloride clearance studies pointed to the idea that salicylate and chloride compete for sodium in renal excretion and that when sodium is limited both are retained to produce a primary fixed acid acidosis.

80. TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS WITH PENICILLIN IN OIL AND BEESWAX

WILLIAM S. HOFFMAN, M.D., ITALO F. VOLINI, M.D., AND J. R. HUGHES, M.D.
(BY INVITATION), CHICAGO, ILL.

Eight patients with all the recognized clinical criteria for subacute bacterial endocarditis were treated with daily single injections of 2 ml. of hard Romansky formula penicillin (crystalline potassium penicillin in peanut oil and beeswax*) containing 600,000 units. Six of the patients had one or more positive blood cultures from which pure strains of *Streptococcus viridans* were isolated. No bacteria could be isolated from the remaining two patients. The treatment was continued for forty-two days, the daily injections being given in alternate buttocks. All of these patients had histories and findings of an underlying rheumatic heart disease.

In these eight patients, the treatment was successful. Remission of fever and clinical symptoms occurred early in the treatment, in some cases during the first week. Cultures became negative in all cases, in some cases before the end of the first week, in no cases later than three weeks. Usually there was gain in weight and strength and ameliorization of anemia. One patient with right hemiplegia on admission from cerebral embolism had severe malnutrition and bedsores during the early part of the treatment, even though the cultures became negative. When her diet was supplemented with intravenous amino acids, glucose, and vitamins B and C, she improved rapidly. There were no urticarial reactions to the many injections. In one obese patient, the induration at the sites of injections required heat to alleviate pain. In no other cases were there any significant local or general reactions. The penicillin sensitivity of the isolated bacteria ranged from 0.008 to 0.3 units per milliliter. Plasma penicillin levels ranged from 1 to 4 units at two hours to values of 0.03 to 0.125 at twenty-four hours. Only one zero level was obtained at twenty-four hours.

A ninth patient with subacute bacterial endocarditis from a focus in the bladder and posterior urethra had *Str. viridans* in the blood with a penicillin sensitivity of 4.15 units per milliliter. He was treated with daily injections of 3 ml. of Romansky penicillin (900,000 units) for thirty-four days without success. After a change to 500,000 units of aqueous penicillin every three hours intramuscularly, the patient still had a positive culture on the fourth day of the new treatment.

The use of Romansky formula penicillin for the treatment of subacute bacterial endocarditis is thus a convenient and successful method if the organism is not too penicillin-resistant.

81. TREATMENT OF LOBAR PNEUMONIA WITH PENICILLIN IN OIL AND BEESWAX

ITALO F. VOLINI, M.D., J. R. HUGHES, M.D. (BY INVITATION), J. R. PEPPER, M.D.
(BY INVITATION), AND WILLIAM S. HOFFMAN, M.D., CHICAGO, ILL.

One hundred four consecutive patients entering the Cook County Hospital with lobar pneumonia were treated with daily injections of hard Romansky formula penicillin (crystalline potassium penicillin G in peanut oil and beeswax*). The daily dosage was 1 ml. containing 300,000 units. Seventy patients had typable pneumococci in the sputum; of the remaining thirty-four, some almost certainly had primary virus infections. Sixty-two per cent of all the

*Commercial Solvents Corp., New York, N. Y.

patients showed a satisfactory remission of fever and symptoms within seventy-two hours. Many of these showed this response after one injection. The percentage of good results was somewhat higher in the group of proved pneumococcal origin. There were four deaths, these occurring in patients with serious complications and of the older age groups. Many of the patients who responded slowly had handicapping complications, such as delirium tremens, chronic heart disease, chronic lung infections, and cirrhosis. There was only one urticarial reaction to the penicillin and no local abscesses.

Plasma penicillin concentrations obtained in twenty-five hospital control patients who were administered 300,000 units of the penicillin in oil and beeswax averaged 0.43 unit per milliliter at two hours, 0.11 at six hours, and 0.09 at twenty-four hours. There were three zero levels at twenty-four hours. In the 104 therapeutic cases, 122 determinations at twenty-four hours showed seven zero levels, the bulk of the values lying between 0.03 and 0.125 unit per ml., with an average of 0.10. At two hours the average level was 0.85 unit per milliliter. Since almost all pneumococci are sensitive to concentrations of 0.03 unit per milliliter or less, the levels obtained over the twenty-four hours with the single daily injections should have been therapeutically satisfactory.

The satisfactory results in over 50 per cent of the bacteriologically unproved cases of pneumonia suggests that penicillin therapy is indicated in all cases of pneumonia. However, if no satisfactory results are obtained in forty-eight hours, the case should be clinically re-evaluated.

82. LABORATORY AND CLINICAL OBSERVATIONS ON THE USE OF A NEW SULFONAMIDE—3,4-DIMETHYL-5-SULFANILAMIDO-ISOXAZOLE (NU 445)

PAUL S. RHODES, M.D., FLOYD A. SVEC, M.D. (By INVITATION), AND
JOSEPH H. ROHR, M.D. (By INVITATION), CHICAGO, ILL.

In vitro comparisons of the bacteriostatic activity of sulfadiazine and NU 445 were carried out with synthetic media to eliminate the polypeptide inhibitory factor. It was found that the two sulfa drugs studied were roughly comparable in action against *Escherichia coli*, gamma streptococcus of fecal origin, and hemolytic streptococci. The acetylated forms of the drugs inhibited the growth of *Esch. coli* and gamma streptococcus but required slightly higher concentrations than the free drug. Folic acid was found greatly to inhibit the activity of both sulfadiazine and NU 445 against the gamma streptococcus but not against *Esch. coli*.

In twenty-four patients receiving NU 445 orally and parenterally in doses of 4 to 6 Gm. daily, the average blood level (fifty-three determinations) was 9.10 mg. per cent total and 6.36 mg. per cent free drug. About 30 per cent of the drug was therefore present in the N, conjugated form (acetylated), a figure considerably higher than for acetylated sulfadiazine or sulfamerazine as determined in this laboratory. In two instances in which NU 445 levels were determined on blood and spinal fluid from the same patient obtained the same day the spinal fluid levels were approximately one-half those of the blood levels.

Slightly more than one-half of the drug administered was recovered in the urine, about 35 per cent being present in the acetylated form. These figures closely approximate those obtained with sulfadiazine.

NU 445 was used clinically in 24 cases, including 6 patients with meningitis (meningococcal, 3; pneumococcal, 2; undetermined etiology, 1), 6 with urinary tract infections, 5 with respiratory infections, 2 patients with erysipelas, 1 with

scarlet fever, and 4 with postoperative infections. In 14 the drug was used alone and in 10 it was used in combination with penicillin and/or streptomycin. In no case was a patient's death thought to be due to failure of the drug to control the infection. Both patients with meningococcus meningitis treated with NU 445 alone recovered.

Reactions occurred in four cases, consisting of a generalized dermatitis in one, crystalluria and hematuria in one, and nausea and vomiting in two others. No local reaction resulted from repeated intramuscular injection of the drug (lithium salt) in 10 per cent solution.

83. CLINICAL STUDIES OF INSOLUBLE KETONES AS INTESTINAL ANTISEPTICS

PRELIMINARY REPORT

MICHAEL H. STREICHER, M.D., AND VERA PITTARD (By Invitation)
CHICAGO, ILL.

Since the discovery of the properties of sulfaguanidine by Marshall, Bratton, White, and Litchfield in 1940, it has been shown that many other sulfonamide groups had similar intestinal antiseptic properties. The clinical advantage claimed for the use of compounds that are absorbed slightly or not at all from the intestine is the obviation of side effects.

Recently a new group of compounds was discovered that are absorbed very slowly from the intestine and yet demonstrate antibacterial activity. The group is derived from p-aminobenzene sulfonic acid (a series of insoluble ketones). Ketones Nu201 and Nu404 were studied. The toxicity values are expressed as a single oral dose of 20 Gm. per kilogram tolerated by white mice for ketone Nu201 and 15 Gm. per kilogram for ketone Nu404. We have administered the new agents to patients orally in doses of one tablet three times daily before meals. Ketone Nu201 was administered over a period from seven to twelve days and Nu404 from eleven to forty-nine days. The blood levels for Nu201 ranged from .08 to 1.2 mg. per milliliter and those for Nu404 from .09 to .8 mg. per milliliter.

In our experience Nu201 is apparently toxic to some patients.

Bacteriologic studies in the stools showed a reduction in the intestinal flora in the staphylococci and streptococci groups. The studies on the *Escherichia coli* group were inconclusive. Clinically, the patients experience a reduction in the number of stools per day, disappearance of abdominal cramping, and a decrease in the amount of blood in the stools. In general, our preliminary experience with Nu404 is more favorable. More work is needed to confirm and to extend our present findings.

84. THE COMPARATIVE EFFECT OF VARIOUS ALKALIS AND UREA UPON THE BLOOD CONCENTRATION, EXCRETION, AND CON- JUGATION OF SULFONAMIDES WITH GLUCURONIC AND ACETIC ACID

JOSEPH H. ROHR, M.D. (By Invitation), AND SMITH FREEMAN, M.D.
CHICAGO, ILL.

The most valuable sulfonamide adjuvant would be one which enhances glucuronic acid conjugation, depresses acetylation, and prevents crystalluria. Since sulfonamides conjugated with glucuronic acid are less likely to result in

uroliths and are more antibacterial than acetylated forms according to the literature, it seemed worth while to study the effect of various adjuvants on the conjugation of sulfa drugs with glucuronic and acetic acid.

Sulfadiazine was given orally to one patient and sulfamerazine to the other on alternate three-day periods for two months with various adjuvants. Sodium citrate and sodium lactate dosages were equivalent to 24 Gm. of sodium bicarbonate daily and the dosage of urea was 60 Gm. per day. Glucuronic acid and the sulfa fractions were determined in blood and urine.

Total sulfonamide blood concentrations were slightly reduced by the alkali adjuvants but not by urea. No significant effect of adjuvants on the percentage acetylated was demonstrated.

In most instances blood glucuronic acid was increased by sodium citrate and sodium lactate adjuvants but not by sodium bicarbonate, nor the sulfonamide alone. Urea depressed the blood concentration of glucuronic acid.

Urinary glucuronic acid was increased by both sulfadiazine and sulfamerazine either with or without adjuvants.

In general there were greater increases of urinary glucuronic acid after alkali adjuvants were administered than when urea or no adjuvant was given. These increases above controls, which were taken on days that adjuvants only were given, were calculated to represent equimolar conjugation with sulfonamide.

The percentage of urinary acetylated sulfonamide was less when the alkali adjuvants were given than when urea or no adjuvant was given.

Urea had no effect on blood concentration, excretion, or conjugation. Most of the ingested urea was recovered in the urine. Blood and urine urea nitrogen had returned almost to control levels twenty-four hours after stopping the drug.

The fact that sodium citrate and sodium lactate increase conjugation of sulfadiazine and sulfamerazine with glucuronic acid and decrease conjugation with acetic acid is an additional indication for the use of adjuvant alkali therapy with these drugs.

85. CRYSTALLURIA FOLLOWING SULFONAMIDE MIXTURES AND SULFONAMIDES PLUS ALKALI: A COMPARATIVE STUDY OF 400 CASES

LEOPOLD J. SNYDER, M.D., ELOISE, MICH.

(INTRODUCED BY CHARLEY J. SMYTH, M.D.)

The use of sulfonamides is attended by the danger of renal complications. Lehr (1945) and Flippen (1946) showed that using a mixture of two sulfonamides markedly reduced crystalluria. This occurs because sulfonamide solutions are mutually soluble. Flippen demonstrated that using single sulfonamides, 12 Gm. of sodium bicarbonate are necessary to keep crystalluria incidence equal to that of sulfonamide mixtures.

This study compares the incidence of crystalluria in 200 patients using a mixture of sulfadiazine and sulfamerazine in equal doses to the crystalluria in 200 patients using a sulfonamide with equal doses of sodium bicarbonate. Group I was given a daily total sulfonamide mixture dose of 4 to 6 grams. Group II received 4 to 6 Gm. of sulfadiazine or, in a few cases, sulfathiazole with equal doses of sodium bicarbonate. Group I averaged 59 years in age and

Group II, 52 years in age. Urinalyses were done every other day. No case was included unless the patient had received the drug for at least sixty hours or had developed crystalluria before that time.

In Group I only 20 per cent of the patients developed crystalluria. Those in Group II showed, however, 42 per cent crystalluria. It is further of significance that in Group I, of seventy-three patients over 60 years old, thirteen (22 per cent) developed crystalluria, comparing favorably with the over-all group. In Group II, however, of sixty-four patients over 60 years, thirty-three (52 per cent) developed crystalluria.

It is obvious that the large amount of sodium bicarbonate recommended by Flippen might well be deleterious in many cases, especially in an old age group or in patients with cardiac or chronic renal disease. Although the 20 per cent crystalluria in Group I of this study does not approach the 6 per cent reported by this observer, it is significantly lower than the 42 per cent found in Group II.

It is concluded that the use of a mixture of sulfadiazine and sulfamerazine is superior to the use of a single sulfonamide plus adjuvant sodium bicarbonate because (1) crystalluria is less in all age groups using the mixture and (2) use of the mixture obviates the necessity of using large doses of sodium bicarbonate in cases in which sodium retention is likely.

86. RECTAL ABSORPTION OF PENICILLIN

EMANUEL E. MANDEL, M.D., CHICAGO, ILL.

(INTRODUCED BY HANS POPPER, M.D.)

Lack of conclusive information on quantitative penicillin absorption from the rectum and contradictory statements as to its efficacy have prompted investigation of this subject.

Retention enemas containing 0.1 to 1 million units of penicillin usually produced insignificant antibiotic activity in both blood and urine.

Suppositories prepared by mixing 0.5 to 1.0 million units of penicillin with cocoa butter resulted in therapeutically useful serum levels lasting several hours. The average peak of 0.5 to 1.0 unit per milliliter, respectively, occurred about fifteen minutes following administration. The total excretion of penicillin averaged 6 per cent of the dose given.

Rectal insufflation of 200,000 units of penicillin through an anoscope was followed by serum concentrations of up to 8 units per milliliter after fifteen minutes and by recovery from the urine of 17 to 50 per cent of the penicillin blown into the rectum. The actual excretion ratio is probably better because diffusion and adherence of some powder to the instrument prevent part of the drug from reaching the mucosa. Comparable penicillin levels in serum and urine were found to result from cocoa butter capsules containing dry penicillin in their centers (16 to 35 per cent urinary excretion). The similar use of rectal gelatin capsules generally produced relatively lower and delayed penicillin activity in blood and urine, the latter ranging between 1 and 22 per cent of the dose administered.

Rectal absorption of penicillin per se is highly efficient and equivalent to upper intestinal absorption. Distribution of penicillin in solution above the lower rectum, intimate contact of the drug with cocoa butter, and slow or incomplete disintegration of gelatin capsules are inhibiting factors. The usual

rapidity of absorption rules out any significant interference by enzymatic action. The clinical application of the rectal route depends upon the selection of the most suitable vehicle.

87. STREPTOMYCIN RESISTANCE OF BRUCELLA SUIIS AND EBERTHIELLA TYPHOSA

W. D. SUTLIFF, M.D., AND KATHLEEN MASON, B.A., MEMPHIS, TENN.

(INTRODUCED BY FORD K. HICK, M.D.)

The streptomycin resistance of microorganisms obtained in blood cultures from one patient with undulant fever and from one with typhoid fever was measured and correlated with the effects of streptomycin therapy.

Br. suis was obtained from the blood of the patient with undulant fever six times in ten days before streptomycin therapy and three times in twenty-eight days after streptomycin therapy. Two cultures made during streptomycin therapy were sterile. Treatment with 26.25 Gm. of streptomycin resulting in blood levels of 22 and 25 units per milliliter had no effect on the symptoms of the disease, which were unusually severe. No significant change occurred in the susceptibility of the strains during therapy. All were inhibited in vitro by 1 unit of streptomycin per milliliter with the exception of one slightly more resistant strain that was inhibited by 3 units per milliliter.

E. typhosa was obtained from the blood of the patient with typhoid fever on the seventh day of the disease and again on the forty-eighth day during a relapse. A total of 37 Gm. of streptomycin was administered for nine days from the tenth to the nineteenth day inclusive without effect upon the symptoms of the disease. No change took place in the susceptibility of the strains during treatment as both were inhibited in vitro by 3 units of the streptomycin per milliliter of media.

The association of increased bacterial resistance in vitro with lack of therapeutic effect in vivo that is so common in streptomycin therapy of urinary tract infections, *Haemophilus influenzae* meningitis, and tuberculosis was not found in these cases. Further growth of the two microorganisms in media containing streptomycin led to the development of substantial increase of resistance. Other mechanisms for the lack of therapeutic effect of streptomycin on infections caused by susceptible strains of brucella and eberthella, such as inhibition by body fluids or inability of the antibiotic to penetrate to the sites of infection, must be postulated.

88. THE EXPULSION OF BETA HEMOLYTIC STREPTOCOCCI BY SNEEZING

MORTON HAMBURGER, M.D., CINCINNATI, OHIO, AND O. H. ROBERTSON, M.D.

CHICAGO, ILL.

Jennison's stroboscopic photographs have revealed the important component of a sneeze to be its highly atomized oral discharge, its nasal discharge being either absent or very poorly atomized. The importance of sneezing in the transmission of respiratory disease will depend largely, then, upon (1) the size and trajectories of droplets expelled from the mouth and (2) the concentration of a given respiratory pathogen in the oral and, to a less extent, in the nasal discharge.

Very few experimental data exist regarding (1) the numbers of human pathogens expelled into the air when carriers sneeze, or (2) the important question of how far the droplets which contain these pathogens are propelled and whether or not they remain suspended in the air for any length of time. Data on these points in reference to beta hemolytic streptococci were obtained by culturing the air of an experimental room in which carriers sneezed. Tiny "droplet nuclei" which remain floating in air for some time were captured by three "bubbler" air samplers set up 1.5, 5.5, and 9.5 feet from the subject, with each sampler's inlet three feet above the floor. Large rapidly falling droplets were caught on blood agar plates on the floor next to each bubbler sampler.

Fifteen of twenty carriers sneezed hemolytic streptococci in rapidly falling droplets 1.5 feet but not as far as 5.5 feet. These fifteen carriers expelled none as "droplet nuclei." Two others discharged small numbers of hemolytic streptococci as "droplet nuclei" but none in large droplets, and two dispersed none in any form. Only one carrier discharged large numbers, both as "droplet nuclei" and in large droplets, 1.5, 5.5, and 9.5 feet away. About one-half the alpha or beta streptococci sneezed out as droplet nuclei were still present in the air ten to sixteen minutes afterward. This carrier's saliva contained unusually large numbers of hemolytic streptococci.

That saliva is the transport vehicle for material sneezed into the air was demonstrated by the finding of large numbers of salivary (saphrophytic) streptococci in the air as droplet nuclei in 35 per cent of the experiments and in large droplets during 80 per cent.

These observations demonstrate that only rarely does sneezing play an important role in the direct contamination of the air with beta hemolytic streptococci. It may occasionally play a minor part by contributing to secondary bacterial reservoirs in floor dust, handkerchiefs, and elsewhere.

89. THE CONTAGIOUSNESS OF COCCIDIOIDOMYCOSIS

SOL ROY ROSENTHAL, M.D., CHICAGO, ILL.

Experiments were conducted in three phases to show that coccidioidomycosis is a contagious disease in guinea pigs:

1. Spherule-containing exudates from patients or infected guinea pigs when instilled into the trachea of guinea pigs produced a primary form of the disease very similar to that found in human beings.

2. (a) Spherule-containing exudates obtained from patients and kept in the icebox for periods up to 110 days failed to produce mycelial threads and chlamydospores but retained their spherule forms that were infective to guinea pigs. (b) Spherule-containing sputum exposed outdoors to the shade or the sun with or without earth for periods up to 230 days retained their spherule forms, albeit in a certain percentage of cases mycelial forms were found.

3. In a limited number of cases, normal guinea pigs placed in the same cages with animals infected intratracheally with the spherules of coccidioides immitis became infected.

90. THE EFFECT OF GERMAN MEASLES DURING PREGNANCY

STUART ABEL, M.D. (BY INVITATION), AND T. R. VAN DELLEN, M.D.
CHICAGO, ILL.

A request for letters from mothers who had German measles during pregnancy was included in a syndicated health column. They were asked to state the exact month of gestation that the illness occurred and the effect on the offspring. Over ninety replies were obtained and of these eighty-two were considered acceptable. The series includes two sets of twins, making a total of eighty-four children.

Three stillbirths were recorded from mothers having German measles during the first trimester of pregnancy. Twenty-five of the children were normal at birth. In seven of these the mother contracted the disease during the first trimester, eleven during the second, and seven in the last. Fifty-six of the infants were abnormal at birth, thirty-six with a single defect and twenty with more than one defect. In forty-four (76 per cent) of these the mother told of having German measles during the first trimester of pregnancy, eight in the second, one in the third, and unknown in three. Nineteen had congenital heart disease, seventeen had cataracts, fourteen were deaf, and seven were mentally deficient. Gastrointestinal, eye, spinal, and skeletal abnormalities also occurred in lesser numbers.

The most serious defects or combination of defects occur in women having German measles during the first trimester; less serious and more infrequent during the second. Only one abnormal child was born in the third trimester group. The diagnosis was cerebral palsy and was not considered to be related to the mother's illness.

Statistics obtained reveal that 87 per cent of the babies born of mothers having German measles during the first trimester were abnormal; 42 per cent during the second; and none in the third. These studies confirm previous observations that there is a definite relationship between congenital defects in the child and German measles in the mother.

91. ABDOMINAL ACTINOMYCOSIS

GEORGE C. TURNBULL, M.D., EVANSTON, ILL.

The abdominal form of actinomycosis represents a highly fatal form of the disease with very few cases reported in the literature. The clinical course is long and tedious, if recovery occurs. It is not recognized early, as a rule, since it is usually associated with, or follows, other diseases in which there is marked emaciation, abdominal pain, anorexia, chills, fever, sweats and diarrhea or constipation. The infection frequently extends to the liver, spleen, kidneys, and central nervous system. Recovery occurs in approximately 20 per cent of the cases.

One patient is reported in whom an abdominal infection by actinomycosis occurred after removal of the gall bladder because of recurrent gallstone colic. The clinical course was prolonged over a period of nine months with episodes of chills, fever, and the appearance of multiple granulomatous masses in the abdomen. One mass drained spontaneously through the left Fallopian tube and uterus. Recovery occurred after prolonged use of penicillin and sulfadiazine in massive doses, associated with adequate surgical removal of a granulomatous mass.

92. COMPARATIVE STUDIES ON THE IODINE ABSORPTION OF ANAYODIN, CHINIOFON, DIODOQUIN, AND VIOFORM IN MAN

ALVA A. KNIGHT, M.D., AND JEANNE MILLER, M.S., CHICAGO, ILL.

(INTRODUCED BY RALPH C. BROWN, M.D.)

Since direct methods of assay of these oxyquinoline drugs are impractical, their absorption after oral administration^a was studied indirectly by determining blood iodine levels. Two hundred eighty blood iodine determinations were made as follows: before the drugs were started and on the third, the seventh, and the tenth days. No initial level before the drug was taken was higher than 17 gammas of iodine per 100 milliliters. The anayodin average was 94 on the third day, 102 on the seventh day, and 102 on the tenth day. The chiniofon average was 85 gammas on the third day, 87 on the seventh day, and 81 on the tenth day. The vioform average was 297 gammas on the third day, 444 on the seventh day, and 393 on the tenth day. The diodoquin average was 651 gammas on the third day, 692 on the seventh day, and 615 on the tenth day. Consideration was given to diarrhea and other factors possibly influencing absorption. In recommended therapeutic dosage chiniofon and anayodin gave the lowest, vioform the next lowest, and diodoquin the highest absorption levels of iodine. In terms of absorbability as measured by iodine intake and percentage recovery in the blood, vioform is the highest, diodoquin next highest, and anayodin or chiniofon third highest.

The absorption was uniform for each drug and was highest on the seventh day and then declined slightly by the tenth day. The drugs were not cumulative and not toxic. This proved absorption of these drugs raises the question of their effectiveness on amoebae deep in the walls of the intestine or in other parts of the body. It likewise shows that none of them are wholly nonabsorbable. They probably destroy no cysts but act on trophozoites only, thus preventing cyst formation.

93. THE EFFECT OF SERUM PROTEIN DEPLETION ON WATER AND SALT EXCRETION AND SENSITIVITY TO PITUITRIN

J. S. SCHWEPPE, M.D. (BY INVITATION), AND SMITH FREEMAN, PH.D., M.D.
CHICAGO, ILL.

Dogs were depleted of protein by a combination of a 4 per cent protein diet and daily plasmapheresis. The effect of serum protein depletion has been investigated with respect to (1) the excretion of water, (2) the excretion of chloride, (3) the extracellular fluid volume, (4) the glomerular filtration rate, and (5) sensitivity to pituitrin.

Plasmapheresis and low protein diets decreased the total plasma proteins from control values of 5.5 to 7.0 Gm. per 100 ml. to 3.5 to 4.5 Gm. per cent; albumin from control values of 3.9 to 2.7 to 1.31 to 1.92 Gm. per cent.

Serum protein depletion had the following effect on the dogs studied: (1) The time required to excrete 50 per cent of ingested water was increased in all dogs following depletion. (2) Protein depletion had no effect on the daily twenty-four hour excretion of chloride. (3) Protein depletion did not appear to alter the twenty-four hour excretion of chloride after the oral administration of 50 c.c. per kilogram of a 0.85 per cent saline solution. (4) During de-

^aDose given: Vioform, 0.25 Gm. three times daily; all others, 0.75 Gm. three times daily.

pletion the extracellular fluid volume increased slightly in all dogs. (5) The glomerular filtration rate was reduced in all dogs. (6) The urinary suppression produced by pituitrin was increased slightly in all dogs. (7) No gross edema or ascitic fluid was present on autopsy. (8) Serum protein depletion had little effect on the histologic appearance of the liver and kidney except for a loss of cytoplasm in the polygonal cells of the liver.

94. THE DETERMINATION OF THE NITROGEN BALANCE INDEX OF A NEW LYOPHILIZED CASEIN ACID HYDROLYSATE IN PROTEIN-DEFICIENT PATIENTS

WILLIAM S. HOFFMAN, M.D., DONALD D. KOZOLL, M.D., W. T. MOK, M.D. (BY INVITATION), AND HANS POPPER, M.D., CHICAGO, ILL.

In a study of the clinical acceptability of a new lyophilized casein acid hydrolysate from which some of the glutamic and aspartic acids had been removed (Amino Acids, I.C.),* nitrogen balances with progressively increasing quantities of the product were carried out in twenty patients with chronic protein deficiency. The material could be injected intravenously in a 10 per cent solution in water, saline, or 5 per cent solution without reactions if the speed was kept below 60 drops per minute. The caloric intake was maintained at about 2,000 calories chiefly with orally administered carbohydrate.

Positive nitrogen balance was obtained in nineteen of the twenty patients studied. The nitrogen intake required to produce nitrogen equilibrium varied from 42 to 340 mg. per kilogram per day, averaging 129 mg. per kilogram, with a standard deviation of 51 per cent. The values were directly proportional to the magnitude of the nitrogen excretion on a protein-free diet, as Allison had found in protein-depleted dogs.

The curve of nitrogen balance in the range of negative and low positive balance was found to be a reasonably good straight line in thirteen experiments. In the remaining six, straight lines could be drawn but were not so well defined. In the region of high positive balance, the curves tended to level off, indicating a ceiling of utilization.

The slope (K) of these lines is the nitrogen balance index of Allison and is a measure of the biologic value of the protein. It averaged 0.68, with a standard deviation of 24 per cent. In the thirteen more precise cases, K averaged 0.66, with a standard deviation of 20 per cent. The nitrogen balance index was therefore a more consistent and more reliable measure of the quality of the protein than the nitrogen intake requirement at equilibrium. The average K value of 0.68 indicated a good protein product. Other experiments show that the biologic value of the protein product was still higher if administered orally.

Serum protein concentrations and total circulating protein were not appreciably increased during the short period of study, results of which confirmed earlier impressions that a much more intense and protracted regimen of protein therapy was required to alleviate severe chronic protein deficiency.

*Prepared for intravenous injection by the Interchemical Corporation.

95. THE EFFECT OF THE RATE OF ADMINISTRATION OF AMINO ACID PREPARATIONS ON THE URINARY WASTAGE OF AMINO ACID NITROGEN

CHARLEY J. SMYTH, M.D., STANLEY LEVEY, PH.D. (BY INVITATION), AND
ANDREW G. LASCHAK, M.D. (BY INVITATION), ELOISE, MICH.

Amino acid mixtures administered intravenously are tolerated at rates exceeding those of casein hydrolysates. This is of practical importance in reducing the time that the patient is kept inactive during intravenous protein alimentation. This study was designed to determine whether the advantages gained by the rapid infusion might be offset by an increased urinary loss. Three different amino acid preparations were studied: Preparation I was an enzymatic hydrolysate of casein (10 per cent Amigen); Preparation II, an acid hydrolysate of casein (Parenamine 15 per cent); and Preparation V (VUJN-9, Merck), a mixture of amino acids prepared by the recombination and fortification of fractions of a casein hydrolysate. The test dose was 500 ml., containing approximately 5.4 Gm. of nitrogen. The amount of amino acid nitrogen in the urine was determined for a four-hour period in twenty-nine individuals.

Five patients received all three preparations at a rate of 500 ml. in two hours; subsequently, as a control, these patients received an equal volume of physiologic saline. The total amino acid nitrogen loss was greater after the administration of Preparation I than after the other preparations. This increase was due mainly to the increased spillage of peptide nitrogen. The amount of amino acid nitrogen in the urine following Preparations II and V were approximately the same. The percentage of the administered amino acid nitrogen in the urine following Preparation I was 10.9 per cent; Preparation II, 5.1 per cent; and Preparation V, 3.9 per cent.

Ten patients received Preparations I and II at rates approaching maximum tolerance, Preparation I being given in one and one-half hours, Preparation II in two hours; Preparation V was given in one hour. Usually less amino acid nitrogen appeared in the urine after Preparation V, in spite of its being given at increased rates.

Four patients received Preparation V, first in a one-hour infusion and later in a thirty-five minute infusion. Three of the four patients had less amino acid nitrogen in the urine following the very rapid infusion than after the one-hour injection; the other lost a little more amino acid nitrogen after the slow infusion.

These studies show that the loss of amino acid nitrogen in the urine does not depend on the rate of the administration of the amino acid preparations. Thus, preparations which are well tolerated may be infused at rapid rates without increasing the urinary spillage of amino acid nitrogen.

96. THE EFFECTS OF INFLAMMATION ON THE SEVERITY OF DIABETES

LAWRENCE M. MAY (By Invitation), AND RAYMOND GREGORY, M.D.
GALVESTON, TEXAS

The concept that gluconeogenesis resulting from proteolysis at the site of inflammation enhanced the severity of diabetes mellitus was introduced by Menkin (1941).

An intense inflammatory reaction was induced by the injection of 1.5 ml. turpentine into the pleural cavity of dogs before and after pancreatectomy. First hourly, then daily, blood and pleural exudate glucose determinations were made. In addition, nonprotein nitrogen, urea nitrogen, and amino acid nitrogen in the blood and pleural exudate were estimated daily. In another experiment glucose was given intravenously and glucose values on blood and pleural exudate were determined hourly. In still other experiments insulin or glucose was injected into the pleural exudate and hourly determinations of glucose in the blood and pleural exudate were done.

We found no sudden marked hyperglycemia following the production of inflammation. While the glucose and nonprotein nitrogen components were higher in the diabetic than in the nondiabetic animals, simultaneous blood determinations showed these values to be higher in the blood of diabetic than in that of nondiabetic dogs.

When Menkin's own data were rearranged to show simultaneous blood and pleural exudate values they confirmed our findings.

Our interpretation of our data, as well as that of Menkin's, does not permit the conclusion that gluconeogenesis occurs locally at the site of a chemically induced inflammation in the depancreatized dog.

97. THE ROLE OF HYALURONIDASE IN HUMAN INFERTILITY: PRELIMINARY REPORT

ALLAN C. BARNES, M.D., BENNETT SALLMAN, M.S. (By Invitation), AND
J. M. BIRKELAND, Ph.D. (By Invitation), COLUMBUS, OHIO

Since the initial observation that hyaluronidase is found in considerable quantities in the male ejaculate, a relationship between this enzyme and the process of fertilization has been postulated. While observations on human specimens have been made, these have, in general, been confined to men, rather than to the problem of the infertile couple. The present study was undertaken in an effort to determine more exactly the role of hyaluronidase in human sterility.

These investigations have followed four lines: (1) The transportation mechanism to the Fallopian tubes of hyaluronidase deposited in the vagina has been studied by tissue assay. (2) The time factor involved in such transportation has been investigated. (3) The relative fluorescence of human ejaculate and of hyaluronidase preparations of testicular origin has been determined. (4) In infertile couples, the hyaluronidase level of the ejaculate of the men has been compared with control groups, and insemination has been carried out after the vaginal application of hyaluronidase.

Methods.—

1. Tissue assays of the Fallopian tube and the appendix removed at operation were carried out in four cases to determine the base line level. In four

additional cases, 1,000 units of hyaluronidase were placed in the vagina prior to operation and assays of the tubes and appendices performed.

2. Two thousand units of hyaluronidase were introduced intravaginally prior to laparotomy. The Fallopian tubes were excised individually at known time intervals following this application and, together with the appendix, were assayed for hyaluronidase level.

3. The human male ejaculate is markedly fluorescent. The degree of fluorescence was compared with the hyaluronidase level and with dilutions of hyaluronidase extracted from the testes of bulls.

4. A series of ten barren couples was selected in whom all studies of the wife were negative for any factor contributing to the infertility. Forty-four inseminations were carried out employing the husband's semen after preliminary intravaginal introduction of the enzyme. Counts and enzyme titrations on the husband were compared with similar data of ten men of recent parentage.

Results.—

1. The intravaginal application of hyaluronidase is an effective method of introducing it. The number of units of enzymes per gram of assayed tube was twice that found in the control group. The mechanism, however, must be by blood stream absorption since the appendiceal assays also reveal a sharp increase in the treated group. The appendix is apparently a less efficient absorber of hyaluronidase than the Fallopian tube. (Ratio of 1 to 1.5.)

2. Tubes excised thirty-five minutes after the intravaginal introduction of hyaluronidase show a higher level than tubes excised twenty-five minutes after the enzyme was employed. The time interval required to reach maximum tissue saturation has not been determined.

3. The preparation of hyaluronidase used by us is markedly fluorescent. The fluorescence of prepared hyaluronidase solutions is proportional to the hyaluronidase level. Our series has not been extended sufficiently, as yet, to permit a mathematical correlation between the fluorescence of the ejaculate and the hyaluronidase level. It is possible that fluorometric methods may provide the quickest assay of hyaluronidase levels.

4. The correlations available between the sperm counts, motility, normal forms, and the hyaluronidase levels are discussed. None of the patients, receiving artificial insemination following the administration of hyaluronidase, conceived. It is not felt that this negative finding rules out the possibility of hyaluronidase playing a role in the mechanism of fertility. It does not appear, however, that a deficiency of hyaluronidase represents the explanation for this series of unexplained infertile couples.

98. SERUM PHOSPHATASE IN OSTEOPETROSIS

DWIGHT C. ENSIGN, M.D., DETROIT, MICH.

In the 138 cases of osteopetrosis (Albers-Schönberg's disease; marble bones) reported in the literature, no record has been found of the acid phosphatase level, and very few specific references to normal basic phosphatase are noted.

A case of osteopetrosis who also showed evidence of two other congenital osteopathies (osteopoikilosis and melorheostosis), occurring in a man of 57 years, has been studied in detail, clinically, roentgenologically, and in the laboratory. For nearly two years repeated determinations have been made of serum alkaline and acid phosphatase. The basic phosphatase has always been in the normal range. The acid phosphatase has, with a single exception, been

consistently elevated. On four occasions figures of 10, 10.8, 12.1, and 12.3 King-Armstrong units were obtained—a level considered as diagnostic for carcinoma of the prostate which has broken through the capsule of the gland. However, serial sections of prostatic tissue removed by transurethral resection showed no evidence of malignancy in this patient.

Only one instance has been previously reported in which a significant elevation of blood acid phosphatase has occurred unassociated with carcinoma spreading from the prostate. This was in an 18-year-old girl with hyperparathyroidism who had a greatly increased basic phosphatase at the time. It is granted that radiographic evidence of osteoblastic metastatic lesions from carcinoma of the prostate might well be concealed by the widespread condensing or sclerosing osteopathy found in osteopetrosis. However, the likelihood of one individual having two conditions, one moderately uncommon and the other extremely rare, does not seem great.

The purpose of this communication is to urge that whenever a case of this very rare congenital bone disorder, osteopetrosis, is encountered, observations of serum acid phosphatase be made in an effort to evaluate the findings in this one patient.

99. CEREBROSPINAL FLUID STUDIES IN ARTHRITIS

MAURICE HARDGROVE, M.D., JOSEPH FERLONG, M.D. (BY INVITATION),
GEORGE MURPHY, M.D. (BY INVITATION), MILWAUKEE, WIS.

Cerebrospinal fluid examinations were made in twenty-one patients having various types of arthritis.

There were ten patients in the group who had rheumatoid arthritis; one of these also had rheumatoid spondylitis. Although the ages in this group varied from 23 to 60 years, all of the patients had active lesions and elevated sedimentation rates. The duration of the illness was from two months to twenty years, and a variety of joint deformities were manifest. In one there was a mild disturbance in the colloidal gold curve. This was the most acute and severe case seen during the study. Three of the patients had spinal fluid proteins above 30 but none were above 40 mg. per 100 milliliters. One fluid showed a slight increase in globulin. The patient who had rheumatoid spondylitis in this group showed normal spinal fluid findings.

In five additional patients having rheumatoid spondylitis there were no colloidal gold curve changes; one showed a slight increase in globulin.

No abnormal gold curves were found in four patients with severe osteoarthritis of the spine. In one of these the total protein was elevated to 50, though the Queckenstedt was normal.

One patient with fibrositis (muscular rheumatism) with an elevated sedimentation rate showed no spinal fluid changes.

One patient was considered to have psychogenic rheumatism and showed no spinal fluid abnormalities.

The blood serology and the spinal fluid Wassermann reactions were all negative. The fluid was clear and sterile in all cases and in no case was the cell count above 5.

The spinal fluid findings have not been instructive in this small group of patients.

100. CYTOLOGIC STUDIES OF SPUTUM IN BRONCHOGENIC CARCINOMA

THORNTON SCOTT, M.D., LEXINGTON, KY.

Since April, 1946, various body fluids have been subjected to cytologic study by the method of Papanicolaou.

Sputum from ninety patients with pulmonary lesions has been examined. A brief outline of the methods employed in preparation of specimens is presented.

Positive findings of carcinoma were reported in twenty-three cases. In seven cases confirmation was obtained at autopsy or exploration. Bronchial adenoma rather than carcinoma was found at exploration in one instance and tuberculosis in another. In eleven cases presumptive confirmation was obtained from roentgenographic findings, clinical course, and death. Subsequent course is unknown in three cases. In four cases the sputum was considered suspicious and on further study it was concluded that squamous metaplasia of the bronchial epithelium had resulted from an irritative focus overlying a calcified bronchial node or from bronchiectasis.

Certain diagnostic pitfalls are discussed.

It is concluded that cytologic examination of the sputum when carefully carried out by an experienced observer can be a valuable aid in the diagnosis of bronchogenic carcinoma and can give positive results when bronchoscopy has failed and other studies are inconclusive.

101. CHRONIC BILATERAL BASAL PULMONARY FIBROSIS: (CLINICAL STUDY)

T. D. JOHNSON, M.D. (BY INVITATION), AND BEN E. GOODRICH, M.D.
DETROIT, MICH.

A study has been conducted of the etiology and course of basal pulmonary fibrosis as revealed by x-ray in ninety-nine patients. Special examinations included chest x-ray, electrocardiogram, sputum studies, and vital capacity. When advisable, bronchograms, bronchoscopies, allergy studies, venous pressures, and circulation times were obtained. Patients with sinus or oral infections were excluded. Diagnostic effects of antibiotics were utilized. In suspected cases, treatment for congestive heart failure or allergy was helpful in diagnosis.

The studies revealed that the x-ray finding of bilateral basal fibrosis was associated with specific conditions in eighty-one patients. The causative factors were congestive heart failure, bronchiectasis, basal pneumonitis, pulmonary artery sclerosis, lymphogenous dissemination of gastric carcinoma, infiltrative bronchogenic malignancy, inhalation diseases, cystic fibrosis of the pancreas in children, pulmonary emphysema, bronchial asthma, and fibrosis secondary to x-ray therapy. Fungus disease was not discovered. No case resulted from continued use of a tracheal airway. Also none was related to chronic nephritis, idiocy, mental deterioration, or prolonged unconsciousness. Abdominal compression was associated with basal lung densities. More diffuse and less dense infiltration occurred infrequently in diabetic patients.

No specific etiology was established in eighteen patients (18 per cent). The period of observation extended from six months to ten years. These patients had cough, basal râles, and bilateral basal pulmonary fibrosis. Eleven

were women and seven were men. The average age was 56 years, with extremes of 43 and 73 years. Handicapping dyspnea was present in eleven. Fever was known to be present at the onset in three. It occurred intermittently in three others. Four electrocardiograms showed minor abnormalities. Left bundle branch block occurred once. In one case 16 per cent eosinophilia occurred during a period of fever. Reproduced chest x-rays revealed different degrees of fibrosis. In two instances improvement in the x-ray findings was noted. In one of these, lung puncture was done six years ago.

This subject is presented in the belief that increased and improved diagnostic efforts will result in the discovery of specific etiologies. Lung puncture may be justified. Possibly pulmonary artery sclerosis is the principal unrecognized factor. Some cases represent chronic recurrent infections. Exogenous nutritional deficiency was not suggested by these studies. Thyroid, pancreatic, or other endocrine abnormalities may prove to be of importance. Disturbed tissue metabolism with exudation and proliferation in excess of absorption and drainage may be a factor. The one consistent feature is age with its increased tissue vulnerability.

102. FEVER THERAPY IN HERPES ZOSTER

CLARENCE BERNSTEIN, M.D., AND S. D. KLOTZ, M.D. (By Invitation)
ORLANDO, FLA.

True herpes zoster is generally considered as caused by a varicella-like virus involving one or more posterior root ganglia resulting in pain and inflammation of the corresponding dermatomes. However, any of several diseases which involve the dorsal ganglia in an inflammatory process may give rise to "shingles" and it is important to differentiate this symptomatic group. Other nerves, notably the trigeminal, may be affected.

The typical evolution of the lesion and its specific characteristics are well known, and the therapy of the condition has been polypragmatic, with varying and sometimes indifferent results.

The nature of the causative agent as well as the site of the lesion suggested fever therapy. This was produced by mixed typhoid vaccine injected intravenously. A temperature of 102 to 106° F. was sought, preferably the latter. Usually this was preceded by a shaking chill.

Six of eight patients with true herpes zoster have been so treated, with striking benefit. If treated early, pain disappears promptly and the skin lesions quickly involute. No postherpetic pain has been encountered in the group. The lesions treated were primarily on the chest or the abdomen, although one involved the supraorbital nerve and another the superior cervical.

The selection of cases is important. Elderly individuals, or those with symptomatic herpes, should not be so treated. Late or well-established cases are likely to have a less favorable outcome. There have been no untoward results and postfebrile herpes labialis has been the only complication. Vitamin B₁ has had little effect in modifying or preventing this. However, the slight discomfort entailed is more than offset by the prompt relief of the neuritic pain. Artificially induced fever appears to have a definite place in the therapeutic armamentarium of true herpes zoster.

103. CLINICAL OBSERVATIONS ON THE USE OF THEPHORIN (NU-1504): A NEW ANTIHISTAMINIC AGENT

JOHN L. REYNOLDS, M.D. (BY INVITATION), AND BAYARD T. HORTON, M.D.
ROCHESTER, MINN.

Thephorin is a new antihistaminic agent, originally known as NU-1504, which has been developed in the Roche Research Laboratories.

It is a polycyclic amine, the empiric formula of which is $C_{11}H_{13}N$ (2-methyl-9-phenyl-tetrahydro-1-pyridindene). It belongs to a heretofore unknown class of compounds. The tartrate which we have used in this study is soluble in water and in a 2 per cent aqueous solution; its $pH = 5$.

Experimental studies in animals demonstrate the antagonism to histamine by (1) abolition of histamine-induced contraction in the isolated guinea pig intestine; (2) relaxation of spasm resulting from treatment with acetylcholine or barium in the rabbit intestine; (3) prevention of broncholar contraction and convulsions in guinea pigs exposed to histamine spray; (4) prevention of the hypotensive effect of histamine given intravenously in cats; and (5) reduction in size of wheals produced by intradermal injection of rabbits or human subjects. Studies for toxicity show that the dosage of thephorin which was fatal to 50 per cent of animals compares almost exactly with that of benadryl but that thephorin is less toxic than pyribenzamine. There is no evidence of chronic toxicity in animals.

The purpose of our study has been to investigate the use of this agent in subjects with symptoms thought to be due in whole or in part to the release of H substance. To date, we have treated fifty-two patients with thephorin. Of this group, thirty-two showed evidence of definite improvement and twenty showed no improvement.

In eighteen patients with hay fever, fourteen reported excellent results on a dosage of 100 mg. daily. Of these, only twelve were relieved by benadryl but had to discontinue its use because of a hypnotic effect. Thirteen were relieved by pyribenzamine but stopped taking it because of gastrointestinal symptoms. Four of our patients did not have their symptoms adequately controlled by thephorin, although the dosage was 200 mg. daily. Three of the four subjects also failed to obtain relief with benadryl and pyribenzamine. Nine patients with vasomotor rhinitis were treated, and four had excellent results with clearing of the rhinitis and sinusitis. The remaining five had no improvement. Of six patients with chronic urticaria, one patient showed improvement and five showed no change. In four patients whose urticaria was on the basis of a physical allergy, two experienced excellent results, and in the other two no evaluation could be made. Six patients with histaminic cephalgia were treated. Two of them had definite improvement. Five patients with migraine and nervous tension headaches were given thephorin; only one of them reported good results. One patient with Ménière's disease was not benefited. One patient with Raynaud's disease, one with erythromelalgia of the hands, and one with dermatographia showed improvement.

No serious toxic symptoms have resulted from the use of this drug. One patient complained of drowsiness. In two patients treated over a period of ten months, the results of routine laboratory studies remained unchanged.

This study indicates that thephorin is a useful drug for the treatment of edema problems in which the etiologic factor is probably the release of H substance. Our comparison of this agent with benadryl has demonstrated that some

patients will respond to thephorin when they do not respond to benadryl, that the dosage required for the control of symptoms was at least 50 per cent less, and that there is an absence of unusual toxic symptoms.

104. THE TREATMENT OF MIGRAINE WITH HISTAMINE: REVIEW OF 144 CASES

DOROTHY MACY, M.D. (BY INVITATION), AND BAYARD T. HORTON, M.D.
ROCHESTER, MINN.

One hundred forty-four patients with migraine were treated with histamine therapy at the Mayo Clinic between 1937 and 1945. These patients have been divided into two groups, one of which includes 124 patients treated prior to June, 1945, and the other, twenty patients treated during the period from June through September, 1945. The cases in each series were classified as typical or atypical migraine. Histamine was administered intravenously, subcutaneously, or by both routes. It was not supplemented by any other type of therapy.

Statistical analysis of data on these cases has shown that the migraine syndrome of 23 to 33 per cent of patients was unchanged by histamine therapy. The syndrome of 33 to 50 per cent of patients with typical migraine, and that of 40 to 66 per cent of patients with atypical migraine, showed significant improvement during treatment by the intravenous route. Approximately 60 per cent of migrainous patients, irrespective of the type of migraine, showed significant improvement during the period of subcutaneous administration of histamine. When histamine was administered by both routes, 70 to 85 per cent of patients with typical migraine and 75 to 100 per cent of patients with atypical migraine showed significant improvement during treatment.

Of the eighty-eight patients who exhibited improvement during the period of treatment, and on whom follow-up data were complete, eighty-five experienced a recurrence of the migrainous attacks when the dose of histamine was decreased below an individual critical level. The three patients who had not experienced a recurrence of their attacks of migraine were still taking histamine subcutaneously at the time they reported to us. A tendency was noted for typical migraine to be more refractory to treatment with histamine and to recur sooner after such treatment than atypical migraine.

There appeared to be no constant relationship between either the total dosage or the maximal single dosage of histamine base and the degree or duration of abatement of the migraine syndrome. It was found that migrainous patients, in general, tolerate ten times more histamine base in a single amount administered by the intravenous route than by the subcutaneous route. In migrainous patients there appeared to be a qualitative as well as a quantitative difference between the effects of histamine administered intravenously and when it was given subcutaneously.

The use of histamine may prevent some attacks of migraine in certain cases. The duration of such an effect seems to parallel the duration of administration of adequate amounts of the drug. Histamine does not appear to be specific in the treatment of migraine.

105. MASKED FOOD ALLERGY AS A FACTOR IN THE DEVELOPMENT AND PERSISTENCE OF OBESITY

THERON G. RANDOLPH, M.D., CHICAGO, ILL.

The voracious appetite of the patient who apparently becomes obese as a result of eating an excessive number of times per day has been explained variously as due to habit, the gratification of eating, or as a result of "nervous" influences. Another mechanism, heretofore not considered in respect to obesity, may explain this apparent craving to eat frequently observed in certain patients with chronic food allergy.

If an allergenic food is eaten several times daily, a masked or chronic smoldering allergic reaction may develop which is characterized by an improvement in chronic symptoms occurring immediately after eating a specific food allergen and which persists for approximately two hours but is then followed by a progressive increase in symptoms. These patients learn to avoid sharp reactions by eating the foods to which they are allergic at such frequent intervals as for instance at 10:30 A.M., and 3:00, 5:00, and 10:00 P.M. and occasionally during the night, in addition to their three regular meals. Without such interval feedings these patients are inclined to develop midway between their regular meals any one or several of the following symptoms: a gnawing hunger sensation in the abdomen, nasal stuffiness, inability to concentrate, somnolence, extreme fatigue, tenseness, and "nervousness."

It is of interest that the foods most frequently eaten in between meals are those to which there is the highest incidence of sensitivity; namely, corn, wheat, and milk, all of which, incidentally, are also high in calories.

It is exceedingly difficult for these patients with uncontrolled masked food allergy to adhere to a reduction diet; the majority of obese patients seen have previously failed to do this.

Hoetzel's theory, that excessive appetite is associated with tissue hydration, finds suggestive confirmation in these individuals, for the avoidance of masked food allergens is often followed by a diuresis, the disappearance of clinical evidences of edema, and a sudden decrease in weight, all of which are associated with the cessation of the abnormal appetite and an improved ability to follow through on a reduction diet.

106. THE INCIDENCE OF ALLERGY TO MAJOR FOODS

THERON G. RANDOLPH, M.D., AND LEONA B. YEAGER, M.D. (BY INVITATION)
CHICAGO, ILL.

Two hundred consecutive cases suspected of food allergy and studied by means of individual food tests with corn, wheat, milk, and eggs were selected from the private practice of one of the authors and subjected to analysis. Each patient was fed a single test food under fasting and basal conditions after a four-day preparatory period during which the food to be tested was completely avoided. The incidence and severity of all symptoms were recorded per unit of time prior to and after experimental feeding, each patient remaining under observation for two hours. Total leucocyte determinations were performed prior to and at twenty-minute intervals following the experimental feeding of the first of two doses which were given an hour apart.

The presence of an unmistakable symptom response in association with the food test represented the prime criterion for diagnosis; the presence of a leuco-

penia of 10 per cent or greater occurring in any of the postingestive determinations was regarded as presumptive evidence of sensitivity. Each instance of leucopenia occurring in the absence of symptoms was checked by the cumulative ingestion of the food in question.

In the first 100 cases corn sensitivity was diagnosed by feeding canned corn or corn meal gruel. In the second group of 100 cases corn meal gruel plus corn sugar was used as the test food. The results of these two series indicate that the addition of corn sugar increases the incidence and severity of allergic symptoms occurring during the course of experimental food tests for detection of corn sensitivity.

The data indicate that corn sensitivity ranks in incidence with that of wheat and is followed closely by milk and eggs in the order named allergy to corn being present in eighty-seven cases, wheat in eighty-five, milk in seventy-five, and eggs in sixty-seven.

Patients cannot be depended upon to detect sensitivity to a major food allergen. In this series a major food was suspected correctly of causing current allergic symptoms in only 8.0 per cent of the cases.

The high incidence of corn sensitivity shown by these data make it imperative that corn allergy be considered in all cases suspected of food sensitivity. It is significant that practically all diagnostic elimination diets widely employed in the past have not completely eliminated corn as an allergen.

107. GELATIN AS AN ALLERGEN

THERON G. RANDOLPH, M.D., CHICAGO, ILL.

In view of the reported nonantigenicity of ossein gelatin and the fact that beef gelatin solutions are commonly used intravenously as plasma substitutes, it is of interest to know that even highly refined ossein gelatin preparations may produce symptoms when ingested by beef sensitive patients.

Four patients with beef sensitivity, each diagnosed by the production of acute allergic symptoms during individual food tests with beef, were subjected to individual food tests with commercial Gelatine^a and Gelatine^c employed for intravenous use.

The experimental ingestion of Gelatine (ossein) dissolved in water and taken fasting in two doses of $\frac{1}{4}$ ounce each an hour apart was associated with the following reactions:

Controls

Four patients known not to be beef sensitive—no reaction

Beef-Sensitive Patients

Case 1.—No reaction

Case 2.—Nasal stuffiness, chilliness, dizziness, abdominal distention, and cramps

Case 3.—Fatigue, headache, tinnitus, abdominal distention, nausea, vomiting and diarrhea—the latter persisting two days

Case 3.—Violent paroxysms of sneezing, followed by nausea and severe headache

^aSupplied through the courtesy of the Chas. B. Knox Gelatine Co.

The experimental ingestion of 150 ml. and one hour later 75 ml. of Gelatine of beef origin prepared for intravenous use was associated with the following reactions:

Case 1.—No reaction

Case 2.—Nasal stuffiness, chilliness, scotomas, somnolence, and abdominal distress

Case 3.—Chilliness, muscle aching, marked fatigue, indigestion, headache, and delayed peripheral edema

Case 4.—Not subjected to this test because of the violent nature of reaction to beef and to commercial gelatin.

It is of interest that the beef sensitivity in each of these cases was completely masked and was not suspected by any patient in spite of the high degree of sensitivity which existed. Inquires of undiagnosed patients as to whether or not they are known to be beef sensitive are usually worthless.

Pork sensitivity did not exist in any of the four patients studied as determined by compatible individual food tests with pork (complete absence of symptoms and a trajectory curve of leucocytosis.) In each instance commercial porcine Gelatine was tolerated in individual food testing without symptoms.

108. THE ELECTROENCEPHALOGRAM IN TUMORS OF THE POSTERIOR FOSSA

REGINALD G. BICKFORD, M.D., AND EDWARD J. BALDES, PH.D.
ROCHESTER, MINN.

(INTRODUCED BY GRACE M. ROTH, PH.D.)

The electroencephalographic findings in a group of fifty predominantly adult persons who had tumors of the posterior fossa can be classified as follows: (1) normal records in 6 per cent of cases; (2) paroxysmal rhythms with frequencies of 3 to 7 and 18 to 22 cycles per second, with a tendency to repetitive wave forms and synchronous activity from all parts of the head in 56 per cent, and (3) a less uniform group showing continuous delta rhythms with a frequency of 2 to 6 cycles per second and delta foci unrelated to the site of the tumor in 38 per cent of cases.

Many of the characteristic abnormalities were seen to advantage in transverse leads from homologous parts of the scalp. For instance, in 65 per cent of all records abnormal waves were noted in the interear lead.

The alpha rhythm showed a marked instability of frequency (in excess of 2 cycles per second) in 42 per cent of the whole group, whereas in another 14 per cent the alpha rhythm was completely disorganized by delta waves. A fast activity with a frequency between 18 and 22 cycles per second, either continuous, or in episodes, was present in 20 per cent of records. A further characteristic feature was the inhibition of abnormal activity when the patients opened their eyes. This occurred in 60 per cent of cases.

The group of records which showed paroxysmal rhythms is interesting since the majority of tracings were indistinguishable from those seen in cases of epilepsy; even the classical wave forms were reproduced. These rhythms, however, cannot represent true epileptic activity since clinical epilepsy from these tumors is almost unknown.

The resemblance might be explained on the basis of a common diencephalic origin for the rhythms of epilepsy and those associated with tumors of the posterior fossa. In the latter case, expansion of the third ventricle which is known to be an early event in the progress of tumors of the posterior fossa presumably would initiate the diencephalic disturbance.

From the diagnostic point of view, it is suggested that the occurrence of a rhythm typical of epilepsy in the tracing from a patient without previous or family history of epilepsy should arouse a suspicion of tumor of the posterior fossa.

109. PERNIO: AN INSTANCE OF APPARENT RECOVERY

DOUGLAS DEEDS, M.D., M.S., DENVER, COLO.

This rare case is being reported because of several interesting features. In 1938 the patient, a white woman, 36 years of age, experienced following exposure to cold the onset of recurrent attacks of painful, disfiguring skin lesions on the ankles and lower extremities only. From that time until seen by the author in 1942 a variety of utterly ineffective therapeutic regimes had been tried. The author advanced the diagnosis of pernio in April, 1942. Subsequent corroboration by Dr. Irving S. Wright and by the vascular section of the Mayo Clinic was greatly appreciated, and the assistance so generously offered by these two sources was of inestimable value.

Otherwise the patient was very healthy. Repeated and exhaustive studies failed to reveal any other pathology. Many ineffectual therapeutic agents had been tried. The author urged sympathectomy and used intravenous typhoid vaccine temporarily since it hastened regression of the unsightly blemishes. No permanent effect of any sort was noted following this form of therapy.

In April, 1943, bilateral sympathectomy was performed. Satisfactory interruption of the sympathetic pathways to the lower limbs was proved by post-operative sweating, etc., tests. Despite this the results were unsatisfactory for the recurrent lesions continued to appear upon exposure to cold. The only apparent effect of sympathectomy on the pernio lesions was to accentuate the severity of the pain associated with the lesions. Kodachrome slides demonstrate the lesions before and after sympathectomy.

In an attempt to assist the patient with her distressing problem another theoretical approach was followed. Fractional gastric analyses revealed hypochlorhydria. Dilute hydrochloric acid administered orally three daily during meals controlled long-standing, mild, gaseous indigestion. The patient felt that there was some beneficial effect on the ease of precipitation and severity of the pernio lesions.

Histamine desensitization was then undertaken. The initial dose was 0.05 mg. of actual histamine base subcutaneously three weekly with gradual increase over a two-month period to 0.35 milligrams. Excessive reaction then necessitated reduction in dosage. A maintenance ration of 0.2 mg. three weekly was maintained until the end of cold weather. Despite continued residence at a mile high altitude and repeated and often intentional exposures to cold, no new lesions appeared.

The author wishes to emphasize the need for further investigation of pernio and that sympathectomy was utterly ineffective in this case. An apparently successful therapeutic program is described.

110. CIRCULATORY RESPONSES TO SPINAL AND CAUDAL ANESTHESIA IN HYPERTENSION: RELATION TO THE EFFECT OF SYMPATHECTOMY

I. EFFECT ON ARTERIAL PRESSURE

ROBERT D. TAYLOR, M.D., ROBERT BIRCHALL, M.D., A. C. CORCORAN, M.D.,
AND IRVINE H. PAGE, M.D., CLEVELAND, OHIO

In 1944 we reported before this Society the effects of high spinal anesthesia on arterial pressure and renal circulation in patients suffering from essential hypertension. In most of them induction of anesthesia resulted in a decrease in arterial pressure. On the assumption that the effects on the circulation of high spinal anesthesia were, in large measure, similar to those resulting from sympathectomy (lumbodorsal sympathectomy and ganglionectomy), we suggested that the response of arterial pressure to high spinal anesthesia might aid in selecting patients for this operation. Caudal anesthesia differs from spinal anesthesia in that it does not paralyze the nerve supply of voluntary muscle. Since it paralyzes preganglionic sympathetic fibers, the denervation is very similar to that of sympathectomy. Such considerations led Russek, Southworth, and Zohman to the conclusion that high caudal anesthesia caused reduction in blood pressure in many patients suffering from hypertension which paralleled the effect on arterial pressure of subsequent surgical sympathectomy. They recommended measurement of arterial pressure during high caudal anesthesia as a guide to selection of patients for sympathectomy.

The purpose of this report is to examine the relationship between the effect on arterial pressure of high spinal or caudal anesthesia and the effect of subsequent sympathectomy by the technique of Smithwick.

The effects of caudal and spinal anesthesia on arterial pressure in hypertensive patients are similar. Among forty-three patients, marked decrease in pressure was observed during anesthesia in forty. Blood pressure was persistently decreased by lumbodorsal sympathectomy and ganglionectomy in twelve of these patients. The three patients whose arterial pressures were not decreased by anesthesia were similarly unaffected by operation.

It is concluded that the blood pressure response to spinal and caudal anesthesia has no more than negative value in the selection of patients for sympathectomy. The discrepancy between the effects on arterial pressure of spinal or caudal anesthesia and sympathectomy may be due to the great difference in time during which the effects are observed or to a difference in the type of denervation which each of them causes.

111. PROTEIN METABOLISM IN RHEUMATOID ARTHRITIS

WILLIAM D. ROBINSON, M.D., AND WALTER D. BLOCK, M.D., ANN ARBOR, MICH.

Nitrogen balance studies were carried out on eight ambulatory and afebrile patients with rheumatoid arthritis and on two normal subjects. Attention was centered on the degree of nitrogen retention following change from a low protein ($\frac{3}{4}$ Gm. per kilogram of body weight) to a high protein intake (2 Gm. per kilogram of body weight). Diets were constant for successive three-day periods and observations were made for at least three periods at each intake level. Caloric intake was constant throughout and permitted maintenance or increase in weight in each subject.

At the lower intake level all subjects were in slightly negative or neutral nitrogen balance. The normal subjects showed definite nitrogen retention during the first few days after change to the high protein intake. The response of the patients with rheumatoid arthritis to the increase in dietary protein varied and may be classified in three groups as compared with the controls. In four of the eight, the degree of nitrogen retention did not differ significantly from that of the normal subjects. In two arthritic patients, the magnitude of nitrogen retention and its duration appeared greater than in the controls. The remaining two arthritic patients retained very little nitrogen during the first few days of high protein feeding. The pattern of the nitrogen retention did not appear related to the severity or duration of the arthritis. Greater than normal retention occurred in the patients who were most markedly underweight.

Nitrogen balance was followed on one additional underweight patient with rheumatoid arthritis during a three-month period on a constant diet supplying a liberal caloric and protein intake. The degree of nitrogen retention was not in excess of that expected to accompany the weight gain which occurred.

SUBJECT INDEX

Book reviews are indicated by (B. Rev.) after the page number.

A

- Acetanilid, a critical bibliographic review, 107 (B. Rev.)
- Acetylleoline and potassium sensitivity of striated muscle, effect of alkaloids on, 1374
- Acetylsalicylate therapy of acute rheumatic fever, biochemical findings in, 1528
- Acid, folic, in treatment of aplastic anemia, 139
 - pteroylglutamine, and its hexaglutamyl conjugate, metabolic function of, 3, 23
 - in treatment of pernicious anemia, experience with, 622
 - synthetic, treatment of pernicious and related anemias with, 262
- Acid fast bacilli concentration, Clorox and Tergitol Javelle water mixture for, 210
- Actinomyco-sis, abdominal, 1536
 - penicillin in treatment of, 1495
- Adams Stokes syndrome, vagovagal reflex type of, an unusual, 1520
- Adrenal gland, role of, in immune mechanisms, 1410
- Agglutination of human erythrocytes, differential, 189
 - test for Brucellosis, discrepancies in, as performed with various antigens and as reported from different laboratories, 817
- Air, expired, apparatus for continuous recording of volume of, 1496
- Albumin and globulin fractions in serum, chemical estimation of, 1203
 - and sugar in same measured sample of urine, rapid test for, 1042
- Albumin-globulin ratio in guinea pig serum, micro-method for determination of, 1500
- Alcaligenes faecalis, bacteremia and acute meningitis due to, 1262
- Allergen, gelatin as an, 1548
- Allergy, masked food, as factor in development and persistence of obesity, 1547
 - to major foods, incidence of, 1517
 - to typhus vaccine, 109
- Alloxan diabetes in mouse, 1258
 - effects of, on human pancreas, 347
- Ambulation, early, and related procedures in surgical management, 108 (B. Rev.)
- Amino acid nitrogen, urinary wastage of,
 - effect of rate of administration of amino acid preparations on, 1539
 - preparations and blood amino acid nitrogen level, effect of rate of administration of, on production of nausea and vomiting, 889
- Amphetamine, quantitative determination of, 913
- Anaphylactic shock in egg sensitive individuals following vaccination with typhus vaccine, 109
- Anemia and leucopenia, radiation induced, effect of folic acid on, 1425
 - aplastic, folic acid treatment of, 139
 - following administration of thorotrast, 147
 - chronic, effect of, on renal function as measured by inulin and diodrast clearances, 1433
 - effect of total body irradiation on a pre-existing induced, 311
 - induced macrocytic, of swine, effect of extrinsic factor, liver extract, and folic acid on, 1398
 - pernicious, and susceptibility to gastric neoplasms, 611
 - folic acid in maintenance of, 970
 - pteroylglutamine acid in treatment of, experience with, 622
 - urinary phenols in, 1242
 - sickle cell, normal red blood cells in, survival of transfused sickle cells in normal subjects and of patients with, 1397
- Anemias, megaloblastic, of infancy, changes in bone marrow before and after folic acid therapy, 1217
 - pernicious and related, treatment of, with synthetic folic acid, 262
- Anesthesia, spinal and caudal, in hypertension, circulatory responses to, 1421, 1551
- Aneurysms of coronary arteries due to polyarteritis nodosa occurring in infant, 1513
- Antigen preparations, dried, use of, for testing pneumococcus typing sera, 104
- Antihistamine drugs, effect of, upon serum induced myocarditis in rabbits, 379
- Antihyaluronidase activity of human serum, 1407
- Antiseptics, intestinal, insoluble ketones as, clinical studies of, 1531
- Antitularense serum, 332
- Aortic stenosis, analysis of 106 proved cases, 324
- Aplastic anemia, folic acid in treatment of, 139
 - following administration of thorotrast, 147
- Apparatus and method for obtaining nasal washings, 1016
 - for continuous recording of volume of expired air, 1496
 - for culturing *Neisseria gonorrhoea* under partial carbon dioxide tension, a simple, 576

Apparatus—Cont'd

- for quantitative microcolorimetric analysis in final volumes of 0.15 c.c., a simple, 215
- pulsating perfusion, 300
- Arteriosclerosis and ischemia, ulcer of leg due to, occurring in presence of hypertensive disease, 323
- Arthritis, cerebrospinal fluid studies in, 1512
- experimental production of, attempts at, 1121
- marrow in, study of, 1430
- rheumatoid, protein metabolism in, 1551
- Atrophic gastritis and malnutrition, 1521
- Auricular flutter, unusual instances of, 51

B

- Bacilli, tubercle, cultivation of, from pathologic material in Dubos medium, 842
- Bacteremia and acute meningitis due to *Alcaligenes faecalis*, 1262
- Bacteria in nasal cavity, method for counting, 566
- preservation of, simplified method for, by desiccation in vacuo, 1008
- BAL, effect of, on human lead intoxication, 1423
- on toxicity of gold, 1364
- Barbiturates, susceptibility of rats to various, factors affecting, 540
- Benadryl, action of, in skin of human beings, 334
- Benzydine-negative stools during iron therapy, 181
- Beta-dimethylaminoethyl benzhydryl ether hydrochloride, action of, in skin of human beings, 334
- Beta hemolytic streptococci, expulsion of, by sneezing, 1534
- Biotin during lactation, utilization of, 1462
- Blood and bone marrow findings in renal disease, 1429
- and tissue proteins, microprecipitating unit for, 213
- cells, counting of, by dark-field illumination, 206
- red, diffraction method of measuring, 857
- changes induced by gastrectomy in rat, effect of synthetic *Lactobacillus casei* factor on, 635
- cholesterol and cholesterol esters in, chromatographic separation of, 1163
- clotting time of, effect of methylated xanthines on, 28
- rotating tube method for estimating, 1037
- coagulation during intravenous injection of histamine, 1432
- coagulation-retraction time and its relation to thrombosis, 1424
- flow, effects of diathermy on, clinical and experimental studies, 1511
- grouping sera, potent, production of, 1275
- heparinized in vitro, coagulation time of, 1087
- levels, enhancement of, by caronamide during intramuscular administration of penicillin, 807

Blood—Cont'd

- peripheral, study of sternal marrow and, of patients with plasma cell myeloma, 167
- platelets, variations in, in allergic individuals following the ingestion of test foods, 1395
- pressure in radial and femoral arteries during and after tilting, direct measurement of, 1511
- in rat, new method for indirect measurement of, 1090
- measurement in rat, comparison of, as obtained by use of tail and foot methods and by direct femoral puncture, 1099
- of hypersensitive individuals, effects of diet of rice and fruit juices upon, 1509
- salicylates in, determination of, simple method for, 1282
- transfusion studies, 223
- ultrafiltrate of, experimental method for obtaining an, 461
- Blood-forming organs, giant cells in, structure of, 660
- Body fluids, dihydrostreptomycin and other antibacterial agents in, dilution technique for rapid estimation of, 1378
- magnesium in, photoelectric determination of, 1027
- penicillin levels in, water-soluble preparation for prolonging effective, 832
- X-irradiation, effect of total, on a pre-existing induced anemia, 341
- Bone marrow biopsy from rat, method of, 102
- concentration techniques, evaluation of, 732
- hematopoiesis in, of rats recovering from nutritional anemia, 756
- in megaloblastic anemias of infancy, changes in, before and after folic acid therapy, 1217
- morphology of, 343
- of normal cats, 70
- plasma cells, reticulo-endothelial origin of, in hypersensitive states, 749
- quantitative cytologic study of multiple samples of, taken simultaneously, 741
- Books received, 929, 1044, 1288
- reviewed, 107, 220, 348, 472
- Brucella melitensis* infections, human, in Minnesota, with hogs as probable source, 854
- suis and *Eberthella typhosa*, streptomycin resistance of, 1534
- Brucellosis, active, biopsy of liver in patients with, 315
- agglutination test for, discrepancies in, as performed with various antigens and as reported from different laboratories, 847
- human, specific treatment of, experimental and clinical investigations on, 1408
- Bundle branch block, human, axis deviation in, 1415

C

- Calcium, relation of, to activation of prothrombin and its significance in dicumarol poisoning, 312
- Cardiac factor which increases coronary flow under sympathetic stimulation, 1515
- Caronamide, enhancement of blood levels by, during intramuscular administration of penicillin, 807
of plasma penicillin concentrations by, 818
- Carotid sinus syndrome, hypersensitive, effects of tetraethyl ammonium chloride on a mixed type of, 1491
- Catgut sutures, surgical, sterility of, fluid thioglycollate medium for testing, 1153
- Cats, bone marrow of normal, 70
- Causalgia, relief of, by tetraethylammonium chloride, 1422
- Cells in blood-forming organs, structure of giant, 660
- Cellular gigantism in human erythropoiesis, clinical significance of, 793
- Central Society for Clinical Research, proceedings of nineteenth annual meeting, Chicago, Ill., November 1 and 2, 1946, 311
proceedings of twentieth annual meeting, October 31 and November 1, 1947, 1394, 1508
- Cerebrospinal fluid, potassium content of normal, 1486
studies in arthritis, 1542
- Chemotherapy, modern development of, 221 (B. Rev.)
of filariasis, experimental, 1293, 1304, 1314
- Cholesteremia xanthomatosis, essential normal, unusual case of, 1526
- Cholesterol and cholesterol esters in blood, chromatographic separation of, 1163
- Choline, methionine, and low fat diet, effect of, on life expectancy of patients with cirrhosis of liver, 1522
- Chromatographic separation of cholesterol and cholesterol esters in blood, 1163
- Clorox and Tergitol-Javell water mixture for acid-fast bacilli concentration, 210
- Clotting time of blood, effect of methylated xanthines on, 28
rotating tube method for estimating, 1037
- Coagulation time of blood heparinized in vitro, 1087
- Coccidioidomycosis, contagiousness of, 1535
- Cold pressor test, nature of, and its significance in relation to neurogenic and humoral mechanisms in hypertension, 1420
- Colloidal gold containing radioactive isotope Au^{198} in selective internal radiation therapy of diseases of lymphoid system, 1437
red test for study of hepatic dysfunction, 1273

Colloidal—Cont'd

- sols of manganese dioxide and gold, studies of distribution of intravenously administered, in human beings and dogs using radioactive isotopes, 274
- Colorimeter, Evelyn photoelectric, standardization and adaptation of thymol test of Mackigan to, 1266
- Complement fixation test with lygraum, evaluation of, 1060
of guinea pigs, effect of pregnancy on, 287
- Coproantibody excretion during enteric infection, significance of, 1409
- Corpuseular constants of college women of the North Central States, 419
- Crystalluria following sulfonamide mixtures and sulfonamide plus alkali, 1532
- D
- Dark-field illumination, counting of blood cells by, 206
- Dermal plethysmograph for recording of skin-wheeling reactions, 1387
- Diabetes, alloxan, in mouse, 1258
severity of, effects of inflammation on, 1540
- Diarrheal disease associated with paracolon, outbreak of, 886
- Diathermy, effects of, on blood flow, clinical and experimental studies, 1511
- Dicumarol in experimental myocardial infarction, 1417
poisoning, relation of calcium to activation of prothrombin and its significance in, 342
- Diet of rice and fruit juices, effects of, on blood pressure of hypersensitive individuals, 1509
- Diets, mixed, for dogs, rats, and human beings, comparison of nutritive value of proteins in, 403
- Diffraction method of measuring red blood cells, 857
- Dihydrostreptomycin and other antibacterial agents in body fluids, dilution technique for rapid estimation of, 1378
- Dithiopropanol (BAL), effect of, on human lead intoxication, 1423
- Diuretics, influence of various, on urinary sodium of normal pregnant women, 312
mercurial, comparison of acute cardiac toxicity in animals and effect of ascorbic acid on detoxification in their intravenous administration, 313
oral mercurial, in ambulatory patients with congestive heart failure, 1514
- D-Serine in rat, nephrotoxic action of, 1130
- Downey, Dr. Hal, special issue in honor of, 583
- Drugs, ethylenediamine, comparative antihistaminic activity of some, in guinea pig, 47
N-(α -Pyridyl)-N-(α -Thienyl)-N',N'-Dimethylethylenediamine, a new antihistamine compound, experimental and clinical experiences, 1370

Drugs—Cont'd

- 1-Diethylearbamyl-4-methylpiperazine hydrochloride, effect of, against naturally acquired filarial infections in cotton rats and dogs, 1314
- sedative-hypnotic,
- 3,3-Diethyl-1,2,, study of, 895
- Dubos and Davis medium, modified, for demonstration of antibiotic activity of subtilin against mycobacterium tuberculosis, 837
- media, cultivation of tubercle bacilli from pathologic material in, further observations on, 812
- Duodenal ulcer, nocturnal gastric secretion in patients with, effect of radiation therapy on, 344
- ulcers, effect of enterogastrone on fasting gastric secretion and motility in patients with, 346

E

- Eberthella typhosa, sensitivity of, to penicillin fractions G and X, 190
- Edema, pulmonary, effect of, on susceptibility of mice to pneumococcal pneumonia, 1406
- Egg-sensitive individuals, anaphylactic shock in, following vaccination with typhus vaccine, 109
- Electric shock treatments, electrocardiographic changes after, 1518
- Electrocardiogram in antero-septal myocardial infarction complicated by right and left bundle branch block, form of, 1518
- lead III and lead CF IV of human, effect of a single inspiration in, 1519
- precordial, in left ventricular hypertrophy, 1517
- Electrocardiographic analysis, regional production of myocardial necrosis with, 1416
- changes after electric shock treatments, 1518
- value of, 331
- in tumors of posterior fossa, 1549
- Electrophotometric modification of Folin's method of estimation of uric acid in serum and whole blood, 1382
- Endogenous estrogens, possible relationship of purpura to, 606
- hypovitaminemia A in liver disease, treatment of, 1403
- Enterogastrone, effect of, on fasting gastric secretion and motility in patients with duodenal ulcers, 346
- Enzyme tests, diagnosis of pancreatic disease by, 1107
- Epinephrine-cyclopropane idioventricular rhythms, induction of, role of arterial pressure changes in, 1415
- Epinephrine injection in complete anoxia, pressor response to, inhibition of, 1414

- Erythroblastosis fetalis, studies in, 1330, 1339
- Erythroblasts, radiosensitivity of, 654
- Erythrocyte, corpuscular weight, determination of normal mean, 66
- Erythrocytes, human, differential agglutination of, 189
- Erythropoiesis, human, cellular gigantism in, clinical significance of, 793
- Estrogen therapy, purpura following, 606
- Ethylenediamine drugs, comparative antihistaminic activity of some, in guinea pig, 47
- Evelyn photoelectric colorimeter, standardization and adaptation of thymol test of MacLagan to, 1266
- Exogenous hemochromatosis, 428

F

- Fever therapy in herpes zoster, 1544
- Fevers, malarial and artificial, biochemical studies during, 508
- Fibrin appearance time, 1037
- Fibrinogen deficiency, clinical features and probable etiologic factors, 502
- Filariasis, experimental chemotherapy of, 1293, 1304, 1314
- Fluid thioglycollate medium, its use for testing sterility of surgical catgut sutures, 1153
- Folic acid, conjugated, nonutilization of, in pernicious anemia, 336
- effect of, on radiation induced anemia and leucopenia, 1425
- in maintenance of pernicious anemia, 970
- in treatment of aplastic anemia, 139
- synthetic, treatment of pernicious and related anemias with, 262
- therapy in megaloblastic anemias in infancy, changes in bone marrow before and after, 1217
- in nontropical sprue, 1231
- Folin's method of estimation of uric acid in serum and whole blood, electro-photometric modification of, 1382

G

- Gastric acidity, relationship of, to thiamine excretion in the aged, 118
- function, human, measurement of, 345
- secretion, fasting nocturnal, variability of, in normal individuals and in patients with duodenal ulcer, 1521
- Gastritis, atrophic, and malnutrition, 1521
- Gelatin as an allergen, 1548
- intravenously administered—a toxicity study, 1115
- Gold reaction, a test fluid for control of, 579
- Gramicidin or penicillin, antibacterial activity of minute quantities of, method for showing, 1136
- Growth curves, streak plate method for determining, 1139
- Guinea pig serum, albumin-globulin ratio in, micromethod for determination of, 1500
- pigs, complement of, effect of pregnancy on, 237

II

- Heart block, partial, hyperparathyroidism and, 185
 disease, congenital, arterial oxygen saturation at rest and during exercise, 1508
 failure, congestive, oral mercurial diuretics in ambulatory patients with, 1514
 rates of sodium turnover in patients with, and in normal subjects, 1169
 isolated, perfused mammalian, failure of, to destroy renin and angiotonin, 1482
 rate in rat, determination of, 1284
 Heat and formalin, influence of, upon Rh agglutinin, 178
 Hematopoiesis in bone marrow of rats recovering from nutritional anemia, 756
 Hemoglobinemia and pH of urine, relationship of, to renal damage produced by injection of hemoglobin solutions into dogs, 223
 Hemolytic streptococci in *Macaens rhesus*, role of phagocytosis in resistance, as related to age of granulocytes following primary and reinfection studies with, 878
 Hemorrhagic telangiectasia, hereditary, in association with cerebral manifestations and pulmonary arteriovenous aneurysm, 1401
 Heparin, assay of, 901
 neutralization of, with protamine (salmine), 1396
 tolerance test, coagulation time of blood heparinized in vitro, correlation of results with, 1087
 Hepatic dysfunction, colloidal red test for study of, 1273
 function in infectious mononucleosis, 1523
 neoplasm, malignant, needle biopsy of liver in patients with, 1524
 Hepatitis, chronic and acute, methionine in treatment of, 1525
 infectious and toxic, pathologic and clinical manifestations, 1524
 without jaundice in infectious mononucleosis, 320
 Herniorrhaphy, convalescence following, studies on, 316
 Herpes zoster, fever therapy in, 1544
 Heterophile antibody determination, simplified "qualitative" method for, using capillary blood and a white cell pipette, 1278
 Histamine antagonists, 47, 1370
 blood coagulation during intravenous injection of, 1432
 test for pheochromocytoma, further studies with, 1510
 treatment of migraine with, 1546
 Hyaloplasm, mitochondria and their relation to so-called, 700
 Hyaluronidase, role of, in human infertility, 1540
 Hyperparathyroidism and partial heart block, 185

- Hypersensitive carotid sinus syndrome, effects of tetraethyl ammonium chloride on a mixed type of, 1491
 individuals, blood pressure of, effects of diet of rice and fruit juices upon, 1509
 Hypersplenic mechanism in human disease syndromes, further studies of, 1399
 Hypertension, renal, 221 (B. Rev.)
 present status of therapy of experimental, 327
 spinal and caudal anesthesia in, circulatory responses to, 1421, 1551
 Hypertensive patients pre- and postsympathectomy, twelve-year study of, with reference to renal pathology, 1509
 state, vasomotor tone in, studies on, 1418
 Hypertensive-ischemic ulcers, 323
 Hyperthyroid conditions, ventricular gradient in, 1516
 Hyperthyroidism, differentiation of incipient, 1412
 Hypoproteinemia due to nutritional deficiency, serum proteins in, 130
 Hypoproteinemias, congenital familial, 1424

I

- Infections, acute, serum proteins in, 1092
 Influenza B in Needham, Massachusetts, December, 1945, 367
 study of a localized outbreak preceding the 1945 epidemic, 332
 epidemic, during spring of 1947, results of vaccination against, 1410
 Inorganic phosphorus and phosphatases in normal and human serum, 194
 Instrument for recording multiple pressures in man, 921
 Insulin depression and carbohydrate excitation of pancreatic islets of Langerhans, 1411
 Insulin in plasma and urine, determination of, 1159
 Iodine absorption of anayodin, chiniofon, diodoquin, and vioform in man, comparative studies on, 1537
 Ionizing radiation, morphologic changes in lymphocytes of persons exposed to, 1045
 Iron therapy, benzidine-negative stools during, 181

J

- Jaundice, direct-reacting type, experimental production of, by injection of a preparation of direct-reacting bilirubin, 321
 serum biliverdin concentration in various types of, study of, 481

K

- Ketones, insoluble, clinical studies of, as intestinal antiseptics, 1531
 Kidney, Murray artificial, experiences with, 1434

L

- Laboratory methods, 76, 196, 296, 444, 548, 901, 1008, 1136, 1266, 1378, 1496
- Lactation biotin during, utilization of, 1462
- pantothenic acid during, utilization of, 1454
- Laetobacillus casei* factor, occurrence of combined system disease in persons with pernicious anemia during treatment with, 335
- synthetic, effect of, on blood changes induced by gastrectomy in rat, 635
- Leucemia, effect of urethane on, 1394
- Leucocyte granules, studies on, after staining with Sudan black B and May-Grünwald Giemsa, 155
- Leukemia, induction of, in eight inbred stocks of mice varying in susceptibility to spontaneous disease, 720
- Lipoid nephrosis, 1435
- Liver, biopsy of, in patients with active *Brucellosis*, 315
- cirrhosis of, life expectancy of patients with, effect of choline, methionine, and low fat diet on, 1522
- prognostic value of biopsy in, 1526
- disease, endogenous hypovitaminemia A in, treatment of, 1403
- extract, effect of, in urinary phenols in normal subjects, 1248
- needle biopsy of, in patients with malignant hepatic neoplasm, 1524
- structural and functional alterations of, relation between, 318
- Lygranum*, evaluation of complement fixation test with, 1060
- Lymphocytes, morphologic changes in, of persons exposed to ionizing radiation, 1045
- Lymphocyto genesis in human lymph nodes, 777
- Lymphogranuloma venereum, studies on, 1060
- Lymphoid system, diseases of, colloidal gold containing radioactive isotope Au^{198} in selective internal radiation therapy of, 1437
- tissue, alterations produced in, by pituitary-adrenal cortical secretion, evaluation of, 584
- Lyophilized casein acid hydrolysate in protein-deficient patients, a new, determination of nitrogen balance index in, 1538

M

- MacLagan, thymol test of, standardization and adaptation to Evelyn photoelectric colorimeter, 1266
- Magnesium in body fluids, photoelectric determination of, 1027
- Malaria, effect of oxygen on, 57
- parasites, staining, simple method of, 89
- Malarial and artificial fevers, biochemical studies during, 508
- Malnutrition, atrophic gastritis and, 1521
- Mammalian heart, isolated perfused, failure of, to destroy renin and angiotensin, 1482

- Manganese dioxide and gold, colloidal sols of, studies of distribution of intravenously administered in human beings and dogs using radioactive isotopes, 274
- Mannitol: kinetics of distribution, excretion, and utilization in human beings, 1192
- Measles, German, during pregnancy, effect of, 1536
- Medical jurisprudence and toxicology, 348 (B. Rev.)
- Megaloblastic anemias of infancy, changes in bone marrow in, before and after folic acid therapy, 1217
- Melanuria, effect of tyrosine, tryptophane, and thiouracil on, 1254
- Mercurial diuretics, comparison of acute cardiac toxicity and effect of ascorbic acid on detoxification in their intravenous administration, 313
- Metabolism of women during reproductive cycle, 1454, 1462
- Metachromatic staining of mucus in tissue sections and smears, permanent, 905
- Methionine, effect of, on urinary nitrogen in human beings at normal and low levels of protein intake, 322
- in treatment of hepatitis, 1525
- Methylated xanthines, effect of, on clotting time of blood, 28
- Methyl-bis (beta-chloroethyl) amine hydrochloride therapy, result of, 1431
- Microanalysis of opiates by x-ray diffraction, 94
- Microburettes, Mohr type of, microserew clamp for use with, 918
- Microcolorimetric analysis, quantitative, in final volumes of 0.15 c.c., simple apparatus for, 215
- estimation of plasma proteins, 296
- Micromethod for determination of albumin-globulin ratio in guinea pig serum, 1500
- Microprecipitating unit for blood and tissue proteins, 213
- Microserew clamp for use with Mohr type micro burettes, 918
- Migraine, treatment of, with histamine, 1546
- Mitochondria and their relation to so-called hyaloplasm, 700
- Mohr type of microburettes, microserew clamp for use with, 918
- Mononucleosis, infectious, hepatic function in, 1523
- hepatitis without jaundice in, 320
- Mouse, alloxan diabetes in, 1258
- Mucus in tissue sections and smears, permanent metachromatic staining of, 905
- Murine typhus, serologic response in, as measured by Weil-Felix, rickettsial complement fixation, and rickettsial agglutination reactions, 360
- Murray artificial kidney, experiences with, 1434

- Muscle, striated, acetylcholino and potassium sensitivity of, effect of alkaloids on, 1374
- Mycobacterium tuberculosis, use of modified Dubos and Davis medium for demonstration of antibiotic activity and subtilin against, 837
- Myocardial infarction, analysis of immediate mortality in 572 cases of, 325
- dicumarol in experimental, 1417
- Myocarditis, serum-induced, in rabbits, effect of antihistamine drugs upon, 379
- Myeloma cell cytology revealed by histochemical methods, 1128
- plasma cell, study of sternal marrow and peripheral blood of patients with, 167

N

- Nausea and vomiting, effect of rate of administration of amino acid preparations and blood amino acid nitrogen level on production of, 889
- Nasal cavity, bacteria in, method of counting, 566
- washings, apparatus and method for obtaining, 1016
- Neisseria gonorrhea, culturing, under partial carbon dioxide tension, simple apparatus for, 576
- Nephrotoxic action of *DL*-serine in rat, studies on, 1130
- Nitrogen balance, 437
- metabolism, studies in, 1403
- mustard, preliminary report of a, 1131
- Nocturnal gastric secretion in duodenal ulcer, effect of radiation therapy on, 314
- Nonprotein nitrogen, rapid titrimetric micro-method for determination of, 1034
- Nontropical sprue, folic acid therapy in, 1231
- Nutrition survey of Viennese civilians under United States occupation, 1915, 1470
- Nutritional deficiency, hypoproteinemia due to, serum proteins in, 130

O

- Opiates, microanalysis of, by x-ray diffraction, 94
- Osteopetrosis, serum phosphatase in, 1511
- Oxygen, effect of, on malaria, 57

P

- Pancreas, effect of alloxan upon the human, 347
- Pancreatic disease, diagnosis of, by enzyme tests, 1107
- edema, transition of, into pancreatic necrosis, 1528
- islets of Langerhans, insulin depression and carbohydrate excretion of, 1411
- Parasites, malaria, simple method of staining, 89
- Parasitic organisms, reactions of various, in tissues, to the Bauer, Feulgen, Gram, and Gram-Weigert methods, 76

- Patent ductus arteriosus, surgery in, results of, 329
- Pathology, renal, study of hypertensive patients pre- and postsympathectomy with reference to, 1509
- Pantothenic acid, utilization of, during lactation, 1454
- Pellagra, metabolic complexities of, 428
- Penicillin fractions G and X, sensitivity of *Eberthella typhosa* to, 190
- in beeswax and peanut oil, absorption and therapeutic use, 31
- in oil and beeswax, treatment of lobar pneumonia with, 1529
- treatment of subacute bacterial endocarditis with, 1529
- in syphilis, 472 (B. Rev.)
- in treatment of actinomycosis, 1405
- intramuscular administration of, enhancement of blood levels by caronamide during, 807
- its practical application, 220 (B. Rev.)
- level determinations in urine, anomalous findings in, 1356
- levels in body fluids, a water-soluble preparation for prolonging effective, 832
- plasma concentrations, enhancement of, by caronamide and sodium benzoate, 818
- rectal absorption of, 1533
- streptomycin, trivalent organic arsenicals, and other bactericidal and bacteriostatic agents, assay of, 411
- Peptic ulcer, combined antacid therapy in, 1527
- Peripheral vascular diseases, 222 (B. Rev.)
- Peritoneal irrigation for acute renal damage following incompatible blood transfusion, 988
- in treatment of renal failure due to transfusion reaction, 982
- Pernicious anemia and susceptibility to gastric neoplasms, 644
- conjugated folic acid in, nonutilization of, 336
- folic acid in maintenance of, 970
- occurrence of combined system disease in persons with, during treatment with the *Lactobacillus casei* factor, 335
- pteroyl hexaglutamyl glutamic acid (vitamin B₁₂ conjugate) in, 337
- pteroylglutamic acid in treatment of, experience with, 622
- treated with synthetic folic acid (pteroyl glutamic acid), combined system disease and hematologic relapse occurring in, 1426
- treatment of, with pteroyl glutamic acid, 1427
- urinary phenols in, 1242
- Pernio: an instance of apparent recovery, 1550
- Phagocytosis, role of, in resistance, as related to age of granulocytes following primary and reinfection studies with hemolytic streptococci in *Macacus rhesus*, 878

- Pheochromocytoma, histamine test for, further studies with, 1510
 Phosphatases and inorganic phosphorus in normal human serum, 194
 Photoelectric determination of magnesium in body fluids, 1027
 Piperazine derivatives, effect of, against naturally acquired filarial infections in cotton rats and dogs, 1304
 Pituitrin, sensitivity to, effect of serum protein depletion on water and salt excretion and, 1537
 Plasma and urine, inulin in, determination of, 1159
 cell myeloma, study of sternal marrow and peripheral blood of patients with, 167
 penicillin concentrations, enhancement of, by caronamide and sodium benzoate, 818
 proteins, microcolorimetric estimation of, 296
 Pneumonia, lobar, treatment of, with penicillin in oil and beeswax, 1529
 pneumococcal, susceptibility of mice to, effect of pulmonary edema on, 1406
 primary pneumococcal, evaluation of treatment of, 333
 Pneumococci, differentiation of, from Alpha hemolytic streptococci, modified technique for, using sodium desoxycholate, 572
 Pneumococcus, type III, surface phagocytosis of, 1406
 typing sera, use of dried antigen preparations for testing, 104
 Pneumonectomy, cure of pulmonary arteriovenous fistula with secondary polycythemia by, 330
 Polyarteritis nodosa occurring in infant, aneurysms of coronary arteries due to, 1513
 Potassium content of normal cerebrospinal fluid, 1486
 determinations in health and disease, 1208
 Potency of U. S. P. reference standard for vitamin D, 1251
 Pregnancy, effect of, on complement of guinea pigs, 287
 German measles during, effect of, 1536
 skin in, vascular changes in, progress report on study of, 1400
 Preservation of bacteria, simplified method for, by desiccation in vacuo, 1008
 Pressure in portal vein, factors influencing, as measured in intact animal, 1401
 Pressures in man, multiple, instrument for recording, 921
 Protein metabolism in rheumatoid arthritis, 1551
 Protein-deficient patients, nitrogen balance index of a new lyophilized casein acid hydrolysate in determination of, 1538
 Proteins, blood and tissue, microprecipitating unit for, 213
 in mixed diets for dogs, rats, and human beings, comparison of nutritive value of, 403
- Proteins—Cont'd
 plasma, microcolorimetric estimation of, 296
 serum, in acute infections, 1002
 Prothrombin time and variables in the method, 554
 studies on human beings and experimental animals, 410
 Pteroylglutamic acid and certain related compounds, urinary excretion of, 1350
 and its hexaglutamyl conjugate metabolic function of, 3, 23
 treatment of pernicious anemia with, 1427
 hexaglutamyl glutamic acid, utilization of, in pernicious anemia, 337
 Pulmonary arteriovenous fistula with secondary polycythemia, cure of, by pneumonectomy, 330
 fibrosis, chronic bilateral basal, 1543
 infarction, experimental, 1417
 Pulsating perfusion apparatus, 300
 Purpura, essential thrombocytopenic, 618
 following estrogen therapy, 606
 rutin in, 340
- Q
- Quantitative determination of amphetamine, 913
 Quinine, rapid continuous extraction and determination of, 196
- R
- Radiation, ionizing, delivering, to discrete tissues, direct infiltration of radioactive isotopes as means of, 1442
 morphologic changes in lymphocytes of persons exposed to, 1045
 Radioactive isotope Au¹⁹⁸, colloidal gold containing, in selective internal radiation therapy of diseases of lymphoid system, 1437
 isotopes, direct infiltration of, as means of delivering ionizing radiation to discrete tissues, 1442
 phosphorus, ³²P: a six-year clinical evaluation of internal radiation therapy, 943
 Radiosensitivity of erythroblasts, 654
 Rat, blood pressure in, new method for indirect measurement of, 1090
 measurements in, comparison of, as obtained by use of tail and foot methods and by direct femoral puncture, 1099
 bone marrow biopsy from, method of, 102
 DL-serine in, nephrotoxic action of, studies on, 1130
 heart rate in, determination of, 1284
 Recording multiple pressures in man, instrument for, 921
 Red blood cells, diffraction method of measuring, 857
 Renal damage, acute, following incompatible blood transfusion, peritoneal irrigation for, 988
 disease, blood and bone marrow findings in, 1429

Renal—Cont'd

- failure due to transfusion reaction, peritoneal irrigation in, 982
- functions, specific, of glomerular infiltration, maximal tubular excretion (or reabsorption), and "effective blood flow," method of determining, using a single injection of a single substance, 931
- hypertension, 221 (B. Rev.)
 - experimental, present status of therapy of, 327
- Renin and angiotonin, failure of isolated perfused mammalian heart to destroy, 1482
- Reproductive cycle, metabolism of women during, 1454, 1462
- Reticulo-endothelial origin of bone marrow plasma cells in hypersensitive states, 749
- Reticulum staining with Schiff reagent after oxidation by acidified sodium periodate, 910
- Rh agglutinin, influence of heat and formalin upon, 178
 - antibody, activation of the incomplete, by blood serum of full-term and premature newborn infants, 1330
 - two popular fallacies regarding, 423
 - typing, rapid technique for, 1024
- Rheumatic fever, acute, acetylsalicylate therapy of, biochemical findings in, 1528
- Russell viper venom, use of, as means of following anticoagulant action of 3,3'-Methylenebis (4-hydroxy coumarin) in dog, 90
- Rutin in purpura, 340

S

- Salicylates in blood, determination of, simple method for, 1282
- Salmonella cultures, serologic diagnosis of, simplification of, 548
- Schiff reagent, reticulum staining with, after oxidation by acidified sodium periodate, 910
- Schlesinger's test for urobilin in presence of riboflavin and other fluorescent compounds, 1503
- Secretion, pituitary-adrenal cortical, alterations produced in lymphoid tissue by, evaluation of, 584
- Sedimentation rates, normal, in active pulmonary tuberculosis, 526
- Sera, blood grouping, production of potent, 1275
 - pneumococcus typing, use of dried antigen preparations for testing, 104
- Serum, albumin and globulin fractions in, chemical estimation of, 1203
 - antitularense, 332
 - biliverdin concentration in various types of jaundice, study of, 481
 - guinea pig, albumin-globulin ratio in, micro-method for determination of, 1500
 - normal human, phosphatases and inorganic phosphorus in, 194

Serum—Cont'd

- phosphatase in osteopetrosis, 1511
- protein depletion, effect of, on water and salt excretion and sensitivity to pituitrin, 1537
 - fraction responsible for thymol turbidity test, 314
- proteins in acute infections, 1002
 - in hypoproteinemia due to nutritional deficiency, 130
 - studies in, 1203
- Shigella, rapid identification of, in public health laboratory, 349
- Sickle cells, survival of transfused, in normal subjects and of normal red blood cells in patients with sickle cell anemia, 1397
- Skin in pregnancy, vascular changes in, progress report on study of, 1400
- Skin-whealing reactions, dermal plethysmograph for recording, 1387
- Sodium benzoate, enhancement of plasma penicillin concentrations by, 818
 - potassium and, determinations in health and disease, 1208
 - turnover, rates of, in normal subjects and in patients with congestive heart failure, 1169
- Sprue, nontropical, folic acid therapy in, 1231
 - vitamin M group (fermentation factor) in, evidence for activity of a second member of, 387
- Sputum, cytologic studies of, in bronchogenic carcinoma, 1543
- Staining malaria parasites, simple method of, 89
 - permanent metachromatic, of mucus in tissue sections and smears, 905
 - reticulum, with Schiff reagent after oxidation by acidified sodium periodate, 910
- Sterility of surgical catgut sutures, fluid thioglycollate medium for testing, 1153
- Sternal marrow, quantitative cytologic study of multiple samples of, taken simultaneously, 741
- Stilbestrol, hypersensitivity to, purpura following estrogen therapy, with particular reference to, 606
- Stools, benzidine-negative, during iron therapy, 181
- Streak plate method for determining growth curves, 1139
- Streptococci, beta hemolytic, expulsion of, by sneezing, 1534
- Streptomycin containing a histamine-like factor, pharmacodynamic effect in man, 42
 - resistance of *Brucella suis* and *Eberthella typhosa*, 1534
- Subtilin, antibiotic activity of, use of modified Dubos and Davis medium for demonstration of, against mycobacterium tuberculosis, 837
- Sudan black B and May-Grünwald Giemsa, leucocyte granules after staining with, studies on, 155

- Sulfon- and sulfanilamide derivatives, anti-bacterial activity of some, 1361
- Sulfonamide, laboratory and clinical observations on use of a new, 1530
- mixtures and sulfonamides plus alkali crystalluria following, 1532
- Surgical management, early ambulation and related procedures in, 108 (B. Rev.)
- Syndromes, human disease, hypersplenic mechanism in, further studies of, 1399
- Syphilis, penicillin in, 472 (B. Rev.)

T

- Telangiectasis, hereditary hemorrhagic, in association with cerebral manifestations and pulmonary arteriovenous aneurysm, 1401
- Temperature and humidity, sudden changes in environmental, physiologic adjustments to, of healthy young subjects and cardiac patients, 1508
- Test fluid for control of gold reaction, 579
- Tetrathylammonium chloride, effect of, on blood flow in extremities of normal individuals, 1419
- on mixed type of hypersensitive carotid sinus syndrome, 1491
- relief of causalgia by, 1422
- ion, evaluation of vasomotor tone in animals and man by means of, 311
- Thiamine excretion in the aged, relationship of gastric acidity to, 118
- Thiouracil and propylthiouracil, comparative clinical study of, 392
- Thorotrast, aplastic anemia following administration of, 147
- 3,3-Diethyl-2,4-dioxotetrahydropyridine, study of, 895
- 3,3'-methylenebis (4 hydroxyecoumarin), effect of, on vitamin A deficient ducks, 532
- 3,3'-methylenebis (4-hydroxyecoumarin) in dogs, use of Russell viper venom as a means of following anticoagulant action of, 90
- 3,4-Dimethyl-5-sulfanilamido-isoxazole (NU 445), laboratory and clinical observations on use of, 1530
- Thrombocytopenic purpura, essential, 618
- Thrombosis, blood coagulation-retraction time and its relation to, 1424
- Thymol test of MacLagan, standardization and adaptation to the Evelyn photoelectric colorimeter, 1266
- turbidity test, mechanism of, 475
- serum protein fraction responsible for, 314
- Tissue, local injury to, quantitative hypothermal method for, 1512
- lymphoid, alterations produced in, by pituitary-adrenal cortical secretion, evaluation of, 584
- Tissues, reactions of various parasitic organisms in, to the Bauer, Feulgen, Gram, and Gram-Weigert methods, 76

- Titrimetric micromethod, rapid, for determination of nonprotein nitrogen, 1034
- Toxicity of gold, effect of 2,3-dimercaptopropanol on, 1364
- Transfusion reaction, renal failure due to, peritoneal irrigation in treatment of, 982
- Tubercle bacilli, cultivation of, from pathologic material in Dubos media, further observations on, 842
- Tuberculosis, active pulmonary, normal sedimentation rates in, 526
- mycobacterium, use of modified Dubos and Davis medium for demonstration of antibiotic activity of subtilin against, 837
- 2,3-Dimercaptopropanol (BAL), effect of, on toxicity of gold, 1364
- Typhus vaccine, vaccination with, anaphylactic shock in egg-sensitive individuals following, 109
- Tyrosine, tryptophane, and thiouracil, effect of, on melanuria, 1254

U

- Uleers, hypertensive-ischemic, 323
- Ultrafiltrate of blood, experimental method for obtaining an, 461
- Uremia, treatment of experimental, by intestinal lavage, 1434
- Urethane, effect of, on leucemia, 1394
- experiences with, in malignant disease, 1431
- Uric acid in serum and whole blood, estimation of, by elctrophotometric modification of Folin's method, 1382
- Urinary excretion of pteroylglutamic acid, 1350
- nitrogen, effect of methionine upon, in human beings at normal and low levels of protein intake, 322
- phenols in normal subjects; effect of liver extract, 1248
- in pernicious anemia, 1242
- sodium of normal pregnant women, influence of various diuretics on, 312
- Urine, albumin and sugar in same measured sample of, rapid test for, 1042
- diurnal excretion of urobilinogen in, of normal subjects and of patients with Laënnec's cirrhosis, 397
- penicillin level determinations in, anomalous findings in, 1356
- Urobilin in presence of riboflavin and other fluorescent compounds, Schlesinger's test for, 1503
- Urobilinogen, diurnal excretion of, in urine of normal subjects and of patients with Laënnec's cirrhosis, observations on, 397
- U. S. P. reference standard for vitamin D, potency of, 1251

V

- Vaccination against epidemic influenza during spring of 1947, results of, 1410

Vaccination—Cont'd

with typhus vaccine, anaphylactic shock in egg-sensitive individuals following, 109

Vascular changes in skin in pregnancy, progress report on study of, 1400

diseases, peripheral, 222 (B. Rev.)

Vasomotor tone, evaluation of, in animals and man by means of tetraethylammonium ion, 311

in hypertensive state, studies on, 1418

Vein, portal, pressure in, factors influencing, as measured in intact animal, 1401

Ventricular gradient in hyperthyroid conditions, 1516

Viper venom, Russell, use of, as means of following anticoagulant action of 3,3'-methylenebis (4-hydroxycoumarin) in dog, 90

Vitamin A deficient ducks, effect of 3,3'-methylenebis (4-hydroxycoumarin) on, 532

B₆ conjugate, utilization of, in pernicious anemia, 337

Vitamin—Cont'd

C status of human subjects, evaluation of, 124

D, U. S. P. reference standard for, potency of, 1251

M, fermentation factor, in spruce, evidence for activity of a second member of, 387

W

Water-soluble preparation for prolonging effective penicillin levels in body fluids, 832

Weil-Felix, rickettsial complement fixation, and rickettsial agglutination reactions, serologic response of murine typhus as measured by, 360

X

Xanthines, methylated, effect of, on clotting time of blood, 23

Vaccination—Cont'd

with typhus vaccine, anaphylactic shock in egg-sensitive individuals following, 109

Vascular changes in skin in pregnancy, progress report on study of, 1100
diseases, peripheral, 222 (B. Rev.)

Vasomotor tone, evaluation of, in animals and man by means of tetraethylammonium ion, 311

in hypertensive state, studies on, 1418

Vein, portal, pressure in, factors influencing, as measured in intact animal, 1101

Ventricular gradient in hyperthyroid conditions, 1516

Viper venom, Russell, use of, as means of following anticoagulant action of 3,3'-methylenebis (4-hydroxycoumarin) in dog, 90

Vitamin A deficient ducks, effect of 3,3'-methylenebis (4-hydroxycoumarin) on, 532

B₆ conjugate, utilization of, in pernicious anemia, 337

Vitamin—Cont'd

C status of human subjects, evaluation of, 124

D, U. S. P. reference standard for, potency of, 1251

M, fermentation factor, in sprue, evidence for activity of a second member of, 387

W

Water-soluble preparation for prolonging effective penicillin levels in body fluids, 832

Weil-Felix, rickettsial complement fixation, and rickettsial agglutination reactions, serologic response of murine typhus as measured by, 360

X

Xanthines, methylated, effect of, on clotting time of blood, 28
